Introduction to Volumes 1 and 2

We have tried in these two volumes to cover most of the major topics in visual neuroscience, starting from molecular fundamentals and progressing to perception and cognition. We are fortunate to begin with an essay by Gerald Westheimer, one of the founders of the modern field and a scholar of great depth. The first volume continues with chapters on visual ecology and the mechanics of vision in animals other than mammals – comparative subjects that should inform thinking about all aspects of vision in any species. Our colleagues in those areas have outdone themselves and we are grateful for their thorough and entertaining contributions.

The chapters on the mammalian retina are, in general, shorter and more focused. In selecting the authors we have sought the leaders and innovators in each specialized area and we are fortunate that so many of them are represented here. We have urged them to provide continuity in their chapters and believe that they succeed in creating a deep and coherent portrait of the circuitry and fundamental functions of the retina. The final chapters of this volume leave the retina and enter the brain. They ask: where does the output of the retina go next, and what happens to it in the early stages of central vision? Here, we begin to encounter some of the limitations of current methods, notably that studies of visual coding have lagged behind the gains made using molecular and imaging techniques. A striking example is our inability to specify the different visual coding patterns transmitted to the brain by the approximately 12 structural types of retinal ganglion cells. Current approaches to the coding problem are illustrated in several chapters; but the problem is far from solved and represents a major task for the next generation.

The second volume moves beyond brain structures and mechanisms involved in light detection, retinal processing, and low-level analysis of visual image features, to address central representations associated with the perceptual interpretation of visual images. In recent years, visual neuroscience has made great strides in understanding how salient visual attributes are represented in the cerebral cortex. Recent advances are reflected here in an extended series of chapters written by leaders in their respective subfields, which collectively explore the cortical representations of luminance, color, motion, and shape. Consistent with one of the major recent trends in the field, these chapters do a fine job of integrating data and comparing perspectives gained via visual psychophysics, neurophysiology, and functional brain imaging.

In addition to representing and abstracting key properties of visual attributes, such as color and motion, vital processing stages in the visual cortex include (i) extracting the spatial layout of surfaces in the visual scene and (ii) recognizing objects. The former falls under what has come to be called 'mid-level visual processing' and recent progress is reflected here in a chapter on the topic of surface depth ordering by cues for transparency and occlusion. Object recognition, by contrast, has long been regarded a facet of 'high-level visual processing'. We have included an extended chapter that canvasses this captivating subfield with timely discussions of visual memory and perceptual constancies. One particularly intriguing and well-studied aspect of high-level vision is face recognition, and we have included a chapter that delves into this topic in some detail.

Among the most important discoveries in central visual processing over the past couple of decades is the degree to which neuronal representations of visual attributes are modifiable by shifts of attention and by experience. The field of visual attention has been particularly prolific and we have accordingly included a series of detailed chapters that address varieties of attention and their neurophysiological manifestations in the visual cortex. Perceptual learning – an experience-dependent change in the way visual features are represented –

is an emerging area of study, and we have included a chapter that nicely interweaves evidence regarding perceptual effects, neuronal response properties, and underlying mechanisms.

Finally, one of the main functions of visual processing is to influence movements of the body. Sensorimotor integration and plasticity are broad areas of study, which deserve their own volume, but we have included herein an article on a topic that is both representative of the field and one of its most deeply plowed zones – the vestibulo-ocular reflex (VOR).

The breadth and depth of topics addressed by the chapters in these two new volumes on the visual system attest to the fact that this field has developed greatly since the time Donald Hebb observed that "we know virtually nothing about what goes on between the arrival of an excitation at a sensory projection area and its later departure from the motor area of the cortex." In recent years, much of this development has been driven by technology – for example, the use of ever-better techniques for cell labeling and tracing of neuronal connections, and the refinement of procedures for recording neuronal activity in behaving animals. A long-awaited bridge has also been extended between the fields of experimental psychology and physiology, which has lead in part to a powerful union of visual psychophysics and cellular neurophysiology.All indications are that the next edition of these volumes will contain chapters that build on still newer technical and conceptual developments, such as the large-scale application of molecular genetic tools to probe visual functions at the systems level, and the use of imaging techniques that enable monitoring of activity simultaneously from large populations of neurons. Indeed, we have much to look forward to.

Richard H. Masland and Thomas D. Albright

Introduction to Volume 3

Producing a handbook, indeed any compendium that purports to represent the state of the art, is a perilous undertaking. Never mind prospective authors who are reluctant to write yet another review, or contributors who enthusiastically accept an invitation but fail to deliver, or the perennially late. Such perils of editorship are expected. The real culprit is the task itself. If a field or subject is mature enough to afford definitive summary, the likelihood is high that it is already stale. If, however, the subject is vibrant and still evolving, trying to summarize it is akin to chasing a mirage. While one writes the gospel according to Peter, Paul is sure to publish a bit that makes Peter's tome somewhat dated. Auditory neuroscience is vibrant and not all the questions are answered. So, as with most books of this sort, this volume provides a glimpse of a field in transition. The reader will find that many chapters hint at some tentativeness. We hope that a lack of final conclusions on some topics will inspire further work.

When we entered the field 35–45 years ago, it was not difficult to master most of what was known about the subject in relatively short order. Then, hearing science was largely the domain of engineers, physicists, and psychologists, and practitioners were few. The subject has meanwhile flourished and expanded to become an integral part of mainstream biology. Relying on all the powerful techniques developed for cell biology and neuroscience with the full incorporation of molecular and genetic approaches, and often introducing some that have been borrowed from the physical sciences, hearing research has emerged as one of the most interesting and complex subjects in all of biology. It is hoped that this volume conveys some of this interest as well as the palpable excitement that permeates the field.

The ear is a remarkable organ. It is a multistage transducer and nonlinear feedback system that conducts mechanical vibrations, slow and fast, first from air to fluid and then from fluid to cells that can convert minute movements to electrical signals that are recognized by the nervous system. The ear could not be more sensitive; if it were, sound would be drowned by thermal noise. It produces a frequency resolution akin to placing 29 new keys between each two adjacent keys of the piano. This book describes some of the special features that allow the ear to perform these feats.

The brain does not receive complete information from the ear directly but uses input from the cochlea to compute what it really cares about, namely where sounds emanate and what they mean. These computational tasks are complicated and are only just beginning to be understood. It is no accident that our external ears sit far apart on our heads; we use the difference in time of arrival to compute the sound's angle of incidence. Those tiny time differences can be used only if the firing of neurons can encode them. Neither is it an accident that our ears are asymmetrical top–bottom and front–back; differences in the way the ears reflect sounds into and away from the ear canal distinguish sounds coming from front or back, up or down. As the head and ears grow, the brain has to keep recalibrating its computations. Perhaps most remarkable, and least well understood, is how a human being uses an onslaught of rapidly changing sounds to learn what another is thinking.

Like the field, the volume evolved too during its planning and production stages. Some subjects were split into smaller chunks, some cameos were added, and several were removed. We allowed, even encouraged, a degree of multiple coverage of certain subjects, particularly those very lively ones where different viewpoints and orientations could be instructive. It is our hope that we have produced an accurate compendium of the field in the first decade of the third millennium that will inspire others to take up the job of discovering how animals hear and understand what is going on in their acoustic environment.

Peter Dallos and Donata Oertel

Introduction to Volume 4

This volume of the *The Senses: A Comprehensive Reference* provides a current review of the chemical senses of taste and smell. Historically, these were considered the minor senses. Descriptions of them were often combined in textbooks both because the natural stimuli are chemicals and because not much was known about them compared with vision and audition. Presumably, they were less studied since it did not seem so bad if humans lost their ability to smell or taste; blindness and deafness were much more serious concerns. However, one might justifiably argue that if all animal life were considered, these are the most important senses. Taste is devoted to a single overwhelmingly important function: it insures that an organism takes in appropriate nutrients and avoids poison. The sense of smell has more varied functions. It too is involved with recognizing food and motivating its intake but it also plays a critical role in monitoring the environment for danger and, perhaps most importantly, in regulating social and sexual activities. Thus, without these two senses most animals would neither eat nor mate! For humans, we have been learning more about the crucial roles taste and smell play in regulating food choice and intake, modulating social interactions, surveying the chemical environment, and providing pleasure. Loss or alteration of smell and taste are not trivial afflictions.

Fortunately, research in the chemical senses is no longer neglected. Indeed, the remarkable rate of progress may, at first blush, even make the idea of a handbook seem absurd. By the time you read these chapters there will be tens of new publications not covered in this book. But in fact it is all those papers that make a compendium like this useful, even if necessarily incomplete. Not long ago one could start out in the fields of olfaction or taste and come up to speed in the literature quite easily. Indeed, for some of us that was one of the attractions of the field. The advent of new techniques, their successful application to questions in chemical sensing, the attraction of investigators from other fields, suddenly transformed the chemical senses from the most mysterious to the most investigated of the sensory systems. Now it is critical to be able to read papers in molecular biology, anatomy, physiology, imaging, psychophysics, genetics, bioinformatics, genomics. . .

So the value of a handbook is as a quick but inclusive reference that will bring even senior investigators rapidly up to speed in an unfamiliar area. In this respect, the contributors to this volume have done an admirable job. Chapters cover all of the above topics in the context of specific systems in olfaction and taste, they cover historical literature (now anything published before 1995 it seems), and provide the kind of background that will facilitate appreciation of the up-to-date advances that appear monthly, if not weekly, in our dynamic field.

This handbook will also, we hope, serve new entrants in the field, especially students and postdoctoral fellows. Each chapter has extensive citations that are an excellent guide to the current literature, and will remain so for many years. The authors have endeavored not only to review the current state of the field, but also to identify important questions and remaining mysteries. Although there have been amazing advances in the past decade and a half, there are even more questions, and more interesting questions, than there were when the last edition of this Handbook appeared.

So, how about the next edition? What will it contain? Will it appear in print or only electromagnetically? What are the advances that will be chronicled in that edition? Who will the chapter authors be? This is a remarkable era in the chemical senses. Our bet is that it is only beginning. We thank the authors for their work to chronicle its current progress and to set the stage for future discoveries.

Gary K. Beauchamp

Introduction to Volume 5

"*There is no coming to consciousness without pain.*" Carl Gustav Jung

It has been argued that pain, unlike audition, vision, somatosensation, and olfaction, is not a primary sense, but instead is more of an emotional experience. Most researchers of pain, however, consider pain to be a complex perception evoked by noxious stimuli. Pain is probably far more complicated than the other perceptual modalities described in this series. For example, in the setting of tissue or nerve injury, where pain is persistent, the stimulus that evokes pain can change. In fact, under these conditions innocuous stimuli can readily evoke the perception of pain.

But even these unusual characteristics do not capture the features that make pain among the most complex of perceptions. The International Association for the Study of Pain defines pain as "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." In other words, although there is a very discrete anatomical and physiological basis for the detection and transmission of messages that are interpreted as painful, what makes the experience of pain so special is that there is always a profound emotional quality to the experience. For all of these reasons, pain is unquestionably one of the most interesting subjects to address in the *The Senses: A Comprehensive Reference*.

Pain in general, and pain research in particular, is especially exciting as it brings together elements of so many disciplines. This volume is comprehensive. It includes a wealth of information on the molecular biology, anatomy, physiology, and biochemical bases of 'pain', both in the normal and injury setting. But this volume also addresses the critical cognitive component of the pain experience, including some of the most provocative cerebral imaging studies that for the first time are providing insights into the gestalt of brain activity that occurs when pain is experienced. There are chapters on the pharmacological basis of the placebo, on the utility of hypnosis for the treatment of pain, and even an essay on consciousness and pain.

This is not a 'how to treat' clinical textbook. Nevertheless, the editors are advocates of the new mantra in the field, namely that *chronic* pain is not a symptom of disease, but rather is a disease entity itself, a disease of nervous system function. Therefore, in addition to covering the fundamentals of acute 'pain' processing, from the nociceptor to cortical activation, we also cover, in depth, the changes that occur in the setting of injury, including molecular, structural, and biochemical alterations in the properties of nociceptors and central nervous system pathways. Some of the particularly intractable clinical pain conditions are discussed. These chapters not only provide insights into pathophysiology but also clues to pain management.

Of course, a variety of compendia have recently appeared, and many also provide comprehensive reviews of the field. With this in mind, the editors have made a concerted effort to produce a final product that is different. Too often the excitement that epitomizes the field of pain research is buried within, or indeed omitted from, the typical edited book. Some textbooks include the proverbial 'box' that highlights an interesting topic, but these are generally very limited. We wanted to bring these topics to the forefront. Our approach is to include, in association with each major chapter, at least one or two cameos that illustrate fascinating and provocative areas of basic and clinical neuroscience that intersect the study of pain.

A few years ago we knew almost nothing about the cortical mechanisms that underlie the pain experience. Today in 2007, some scientists, albeit the minority, believe that cortical imaging can provide an objective measure of the pain experience. A few years ago, the tetrodotoxin-resistant subtype of voltage-gated sodium

channel, NaV1.8, was considered the Holy Grail for the next breakthrough in pain management. How fast things change. The discovery that a loss of function mutation of NaV1.7 underlies a condition of congenital insensitivity to pain and that a gain of function mutation underlies the excruciatingly painful condition of erythromelalgia has dramatically altered the focus, not only of the science community but also of the pharmaceutical industry. The pace of discovery in pain research is indeed remarkable. We hope that this volume conveys the excitement inherent in this discovery process and, most importantly, that it stimulates the next generation of basic and clinical scientists to unravel the mystery of the pain experience.

Allan I. Basbaum and M. Catherine Bushnell

Introduction to Volume 6

When we read the word 'touch' we think of hands: an empty hand extended in friendship, a lover's caress, a mother cuddling her infant child, the 'high fives' of teammates slapping each others' hand celebrating victory in sporting events. Touch means contact between our body and another person, object, plant, or animal. Contact deforms the skin in ways that convey information to the brain about the identity of external entities; their size, shape, compliance, texture, and temperature. Because the hand is the most densely innervated part of the human body, it is not surprising that we use the hand more than any other body part to glean information beyond ourselves that allows us to interact with our surroundings in meaningful ways.

The sense of touch is unique in that it is not merely receptive, but it is crucial for guiding motor behavior. We interact with the environment to acquire tactile information, and use that knowledge to modify the world. Touch is essential for guiding the behavior of our hands. This dual sensory and motor role of touch has been beautifully depicted by the seventeenth century Spanish artist Jusepe de Ribera (1591–1652) in a canvas entitled '*The Sense of Touch*' (Figure 1). Here we see a blind man holding a sculpted head in his left hand as he palpates the face with his right hand. The surface contours and features of the head that are sensed by receptors in the hand are transformed by the brain into a mental image of the object. However, this object is not found in this form in nature, but was actually created by the hand of the sculptor, guided by touch. The painting itself is,

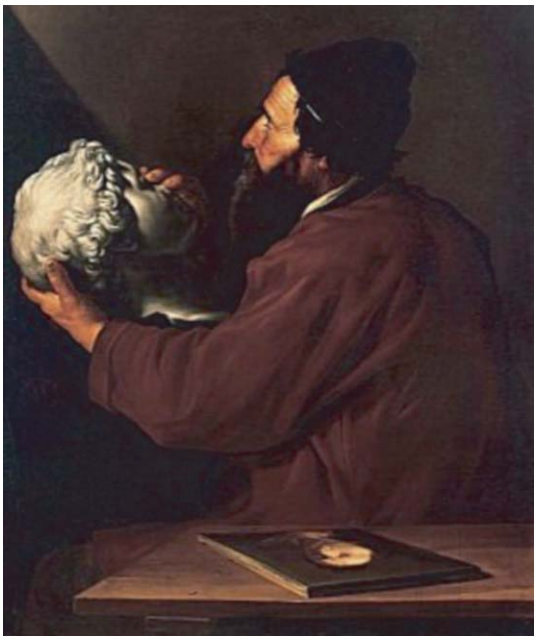

Figure 1 The Sense of Touch, c. 1615–16 by Jusepe de Ribera. Reproduced with permission from The Norton Simon Foundation © 2002.

of course, another work of the hand in which direct vision of the world, or the world of the artist's imagination, is transformed by the actions of the hand into an image on canvas delineated by skilled hand movements.

In this volume we have attempted to summarize current knowledge about the sense of touch. The various chapters have been selected to provide insight into the neurobiological mechanisms that underlie tactile sensations. We begin with an examination of the psychophysics of touch, the ability of humans to perceive the world through deformation of the skin by external stimuli. We then describe the various sensory receptors in the skin that transduce mechanical and thermal events into a pattern of nerve impulses that convey discrete bits of tactile information to the central nervous system. We explore how the information is integrated and transformed in the brain to give rise to conscious sensations of touch. In higher centers of the cerebral cortex, the sensory signals are further transformed by cognitive mechanisms such as attention, experience, and prediction, as well as by motor behaviors as we interact with the world in meaningful and useful manners. These subjective actions allow us to feel what we are particularly interested in, and to shape the information in ways that are useful for accomplishing the desired goals.

Most of the chapters in this volume deal with the sensory capabilities of the hand of humans and monkeys. However, we have also included chapters on touch in other parts of the body, and in other species, to highlight those properties of touch unique to primate hands, and those generalizable to touch as a sensory modality. We hope that this volume will provide a valuable resource to students encountering this subject for the first time, as well as to the expert audience who have contributed so much to our understanding of the sense of touch.

Esther P. Gardner and Jon H. Kaas

Dedication to Volume 4

David V. Smith (1943–2006)

David Smith was prominent among a cohort of taste physiologists born in the 1940s on three continents, who have collectively defined – or trained those who defined – gustatory activity in the central nervous system. They learned from the founders of our discipline: Yngve Zotterman, Carl Pfaffmann, Lloyd Beidler, and Masayasu Sato. Equipped with self-styled microelectrodes, they extended recordings from peripheral axons to the small, medial neurons of this ancient sense and taught us how taste selects from a perilous chemical environment to compose a healthy body.

Even as David made his way from his boyhood home in Memphis to study psychology in Knoxville forces were aligning in a competition that was to become the central motif of his career: labeled-line versus patterning. It was a binary that always concerned David, but never consumed him, as it did others of his era. It was our primary topic of professional conversation when David and I explored the South Pacific for a month in the early 1970s, and still the focus of a chapter we wrote three decades later. However voluminous the data, however sophisticated the analyses, they have never been sufficient to seal a victory, and now the issue, still unresolved if indeed a resolution exists, lies exhausted at the periphery of the field (see Chapter 4.17 A Perspective on Chemosensory Quality Coding by M. Frank)

David was always respectful of the coding arguments from both sides, as he was of those who made them. However, he could never divorce his thinking from the central discovery of gustatory electrophysiology – that taste cells are broadly tuned – and permit himself to favor a labeled-line strategy that would seem poorly suited to that finding. Thus, David remained an advocate of patterning even as he vowed unsuccessfully, three times in my presence, never to entertain the topic again.

David trained with Don McBurney in psychophysics, then with Pfaffmann in the electrophysiological techniques that became central to his life's work. He experimented on blowflies, frogs, mice, rats, rabbits, cats, and humans, but David's primary focus was on the hamster hindbrain. Over 30 years, David generated a body of data from the hamster that complemented each component that others had revealed in rats: anatomical connections, membrane qualities, coding principles, neurotransmitters, and centrifugal influences (see Chapter 4.12

Neurotransmitters in the Taste Pathway by R. Bradley). David's thinking was creative and original; his techniques precise; his analyses sophisticated and unbiased. He did not work in large groups – across all his publications David has a mean of fewer than 1.5 co-authors – but over time he worked with scores of colleagues, learning their techniques, sharing his, and always pressing for deeper understanding (see Chapter 4.15 Central Neural Processing of Taste Information by D. Smith and S. Travers).

His objective pursuit of information absent personal agendas made David a trusted colleague and leader. The Association for Chemoreception Sciences (AChemS; Minneapolis) elected him Executive Chairperson (now 'President') in 1985. David directed the neuroscience program at the University of Wyoming in the 1970s and 1980s, the Taste and Smell Center at Cincinnati in the 1980s and 1990s, served as Vice-Chair of Anatomy and Neurobiology at the University of Maryland School of Medicine in the 1990s and 2000s, then completed his life cycle, returning to Memphis as endowed Department Chair of Anatomy and Neurobiology at the Tennessee Health Science Center. In each role, David was fair, collegial, yet demanding, as he was as Executive Editor of *Chemical Senses*.

David was in the fullness of his personal and professional life, living in the city that had called him home, surrounded by appreciative colleagues and by his wife Michiko, whose devotion David requited. In my last chat with the healthy David in 2005, he expressed as much satisfaction with his life as his modesty would permit. It was all too brief.

Thomas R. Scott

Dedication to Volume 6

During the course of one year, the somatosensory community lost three major colleagues: Kenneth Johnson, Stanley Bolanowski, and Tim Pons. All three had been invited to contribute to this Volume, but sadly they passed away before this was possible. References to their work abound in various chapters, but do not substitute for their unique achievements and voices. We all miss them dearly, and would like to dedicate this Volume to their memory.

1.01 The Visual System and Its Stimuli

G Westheimer, University of California, Berkeley, CA, USA

© 2008 Elsevier Inc. All rights reserved.

1.01.1	Conceptual Foundations	1
1.01.2	The Visual Stimulus	2
1.01.3	The Compression of Information	2
1.01.4	Seeing Objects in Space	3
1.01.5	The Experimental Problem: Efficient Specification of Stimulus Variables	5
1.01.6	Information Theory and Prior Probability	6

Once it became accepted, a millennium ago, that vision takes place not by the emanation of probing rays from the eyes but by the transmission into the eye and acceptance at the retina of light from the outside, the general program of vision research was laid out: learning how to relate our perception of things to the objects generating them.

The outer bounds of this program pose very profound questions indeed, and have commanded the attention of the deepest thinkers. Just what is a valid description of the outside world? How to get a grip on what constitutes a percept? Notions range the gamut from Immanuel Kant's demand that our knowledge of the *Ding an sich* is entirely indirect, predicated on the structure of our mind, to, at the other extreme, the willful ignoring of any subjective content of percepts by behaviorists.

However, if the problem is defined a little more narrowly, it becomes tractable. We accept that there is a world outside of us and that there are commonly agreed-on ways of characterizing it, a job vision researchers leave essentially to physicists. We also accept that all of us have personal experiences that can be grouped under the rubric of percepts, talked about, compared, and – by observing the report and behavior of others, including animals – used as data for scientific investigation.

1.01.1 Conceptual Foundations

A central issue stems from Johannes Mücler's law of specific nerve energy: not how discharges in the optic nerve fibers are initiated, but their central connections characterize a sensory input as visual. From this follows the posing of the question as to the adequate stimulus, a concept widely discussed in the early days of sensory research and defined as the environmental variable for which the energy needed to initiate a response is minimal. For human vision it is the electromagnetic radiation in a one-octave wide band centered on a wavelength around 550 nm. It was called light well before electromagnetic radiation had been invented and had its own stand-alone standard, the candle, whose physical properties were defined only after physicists had come to involve themselves with such devices as radiometers. No better illustration can be found of how natural science begins and then expands around the human experience. Nor of how the visual system has evolved to match what matters in the organism's environment and best enables to deal with it. The wavelength range and maximum sensitivity within it parallels that of the ambient radiation, that is, sunlight for terrestrial animals and shifted toward shorter wavelengths in the case of deep aquatic ones.

By 1860, Fechner, a seminal figure in this area, had enunciated that the task of sensory science is to find a functional relationship between the physical, and the mental worlds and he called it psychophysics. In a nice nineteenth-century touch that has served twentieth-century vision science so well, he allowed the subject to go forward on two separate tracks: the functional relationship between the outside world and some intermediate corporal stages, and then between the latter and the mind. Because not too much was known in Fechner's time about the central neural stages of vision, he left us free to select structures to identify as the intermediate stage. It could be the retina, the primary visual cortex, or other cortical areas. The second part of Fechner's program, the relationship between physiological states of the brain and our conscious experiences, involves questions that vision scientists by and large have laid aside, although a resurgence of interest in consciousness is beginning to change that. One way of

circumventing it has been the short-circuit of substituting overt behavior for the psycho in Fechner's psychophysics – the program of vision research then becomes uncontestable, both to those favoring a severely physicalist approach and to those demanding that subjective experiences be included in the portfolio. It is just that the latter group insist that there is also place for personal, not physically substantiable, observations, say, the unique yellow in the spectrum, or Gestalt grouping. Or, in Hering's memorable phrase, if one wants to figure out what a watch does, it helps, in addition to studying its cogs, wheels, and springs, to look at its face.

1.01.2 The Visual Stimulus

Regardless of the end point, the practice of vision research starts with the world of stimuli. Even the most subject-oriented of vision researchers, Goethe in his *Farbenlehre*, devoted to cataloging light and color experiences, could not entirely dispense with the manipulation of stimuli. Of the three involved class of parameters, time had been standardized since antiquity, for defining the parameters of space we turn to geometry, and for the specifications of light and color to classical physics.

But it is salutary to remember that human vision played a role in the evolution of knowledge in the fields of geometry and classical physics. It is not coincidental that the all-time greats in the physics of light – Isaac Newton, Thomas Young, James Clerk Maxwell, and Lord Rayleigh – all manifested an interest in vision and made notable contributions to it. Neither can the more formal side of defining the outside world, geometry, be seen as proceeding independently of the rules and structure of our visual system. A straight line is not defined by logical inference from previously defined premises – the usual operation within closed logico-deductive system in mathematics – but is an axiom based entirely on intuition. Used in fundamental discussions by thinkers from Kant to Hilbert, the German word *Anschauung* is indispensable here: sometimes translated as apperception, it means an intuitive, unmediated perceptual grasp of something, not further analyzable. There is a component of *Anschauung* in the axioms of geometry and indeed in the representation of space in our mind. The manifold of colors is also three dimensional but it unfolds in an entirely different manner in our mind than the visual space of objects.

At the outset, the most direct physical standards are employed to characterize what impinges on our eyes when we open them, and hence the stimuli used in vision research to probe the visual system. If the specific visual functions to be investigated are not known beforehand, we would in theory want to have available the full panoply of information about the outside world confronting the eyes, namely the temporal sequence and wavelength distribution in the energy directed to the eye from all the points in the three-dimensional object space. This is a five-dimensional manifold (energy in ergs, along with time, wavelength, and the three space dimensions). For most vertebrates, the additional dimension of polarization can be ignored. The coherence property of the radiation, to which in principle some light-detecting mechanisms are not indifferent, seems not to be utilized.

1.01.3 The Compression of Information

Such a complete catalog is outside the capability of any organism to process. Thus compromises have to be introduced to winnow it down. As species evolve, the uptake is narrowed by making choices at many junctions:

- Three hundred sixty degree panoramic vista, or only forwardly directed vision with binocular overlap for purposes of depth perception?
- Equal but limited resolution over the whole field or specialized high-resolution locus with an eye movement scanning ability?
- Fine differentiation in the wavelength dimension or economy in the number of photopigments?
- High sensitivity to weak stimuli and to small differences, or robustness to overload?

In all these cases, a particular balance has been struck between cost of processing and the information available to the animal. In the wavelength dimension, many mammalian eyes manifest a particularly ingenious solution: two separate systems with different portfolios. The energy emitted by a star and directed to the eye might, for spectroscopic purposes, be broken down into erg s^{-1} for as fine a set of wavelength bins as the resolution of the spectroscope permits and should also be detected in as small a quantity as feasible. So we have two parallel systems: scotopic and photopc.

The scotopic system has high sensitivity and, because all the light is funneled through a single photopigment, it has no ability to dissect in the wavelength dimension. It involves a simple light specification: find the product of the incident energy and the scotopic luminosity at each wavelength and arrive at a single number that denotes the stimulus strength for that star (Figure 1). We have an illustration of information compression with its twin consequences: (1) economy of signal transmission (there is only one value – scotopic lumens) and (2) inability to reconstitute the original input (as regards chromaticity, scotopic signals are monovariant).

For photopic vision, the same principle holds, except now the photopic luminosity is used to arrive at the luminance, in lumens, by the same process of multiplication and summing over the spectrum. In addition, trichromacy enters. For purposes of color discrimination, it suffices to calculate two chromaticity coefficients, because light is filtered through just three classes of photopigments and it is the ratio of their output that counts. This is again a process of information reduction, though this time not as severe as for scotopic vision. However, once it is done, the full spectral emission curve has been discarded and cannot be reconstituted. The associated loss of information is best exemplified by the phenomenon of metamerism, in which a whole host of wavelength distributions that yield the same chromaticity coefficients are no longer distinguishable. However, because there is variability in the cone pigments between species, and even among the normal of the same species, not to mention genetic deficiencies, characterizing a stimulus in terms of the standardized color coordinates is inappropriate in some circumstances of thorough color vision analysis.

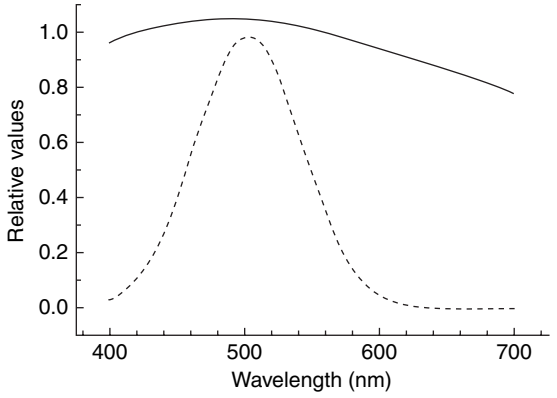

Figure 1 A star like our sun has an emission spectrum (in units of watts, W) given by the solid line. To derive its luminous energy for scotopic vision, the ordinates of each point on this curve are multiplied by the height of the scotopic luminosity curve, shown by the dashed line, at that wavelength and the product summed over the whole spectrum. Units of the luminosity curve are lumens/watt and the product therefore is a single number in luminosity units embodying the stimulus strength of this star for rod vision. The detailed shape of the star's emission spectrum has been discarded in the process and is no longer available. This is an example of compression within a stimulus domain, with the dual consequence of efficiency of operation and loss of information.

Thus the process of compressing information about the world of stimuli is intimately intertwined with the current knowledge of the structure and function of the visual system – when this is still evolving, the process is incomplete and in danger of being circular. This applies also to the physical description of the domain of stimuli. Just imagine if it turned out that some eyes are sensitive to a hitherto unsuspected or perhaps even unknown variable of electromagnetic radiation, say circular polarization or photon entanglement. All previous relevant experiments would then have an element of uncertainty because that particular dimension of a stimulus had been left unspecified. Fortunately, vision science these days is unlikely to be susceptible to such concerns, but other sensory modalities certainly are not.

1.01.4 Seeing Objects in Space

One subset of the visual world that has received more attention than the rest is that of space. As pointed out earlier, there is something special about our appreciation of the layout of stimuli in three dimensions. Regardless of whether we think it has been arrived at through learning or we began with an innate sense of it (i.e., whether we lean toward an empiricist or a nativist standpoint), we all see objects arrayed in different locations simultaneously, there is an extensive quality here that can be counterpoised to those of brightness and color, to which the word intensive is traditionally applied. That this arraying is in three dimensions – no less than three quantities are needed for a full specification – is a given fact, no further analyzable. But the mode of specifying locations within space certainly is, and the subject has been analyzed by some of the finest scholarly and scientific minds.

Since Euclid it has been the convention to posit points as the beginning elements of space, and since Descartes to construct a rectangular coordinate

system to house them. Once an origin has been chosen, three numbers uniquely define the location of a point. For monocular vision it is convenient to set the origin at the center of the eye's entrance pupil and to have the vertical axis accord with gravity, aligning the eye and head with it. But other coordinate systems may at times be more expedient (Figure 2). Where binocular vision is involved, one can place the origin at the bisection point of the line joining the centers of the entrance pupils (or perhaps the centers of rotation) of the two eyes, and draw the radius vector from that point to the object point. The three coordinates could now be r, the distance along the radius vector, and θ and ϕ, the angles of rotation around the vertical and horizontal axes, respectively. Such a construction makes overt that the distance from the observer and the angle made with the head's mid-sagittal plane have more perceptual import than the Cartesian coordinates. One can go even further and define the distance from the observer not by the linear measure along the radius vector but by the angle of parallax between the lines of sight of the two eyes to the object point. Here is a coordinate system based on three angles: laterality, elevation, and binocular parallax. In many instances it may be a better map than any other for the neural representation of space in the primary visual cortex.

It should be noted that the spatial transformations described so far differ only in the specification of coordinates; simple equations relate them. Nor has any compression been introduced, like the one which leads from the full spectral distribution to just one luminosity and two color values. But, of course, the specification of the light-emitting property of the three-dimensional world surrounding an observer, point by point, is an astronomical undertaking and almost never warranted. If the visual mechanism being studied is adequately accessed through one eye, and if the observation distance is kept constant, only two dimensions of visual angle are needed. Further reduction is possible if a repertoire of configurations is utilized, each of which requires only a smaller set of parameters. Paradigmatic is the line, which needs only the coordinates of each end point or, equivalently, coordinates of one end plus length and orientation. A huge range of visual mechanisms, neural and psychophysical, have been investigated with stimuli whose geometrical and luminance properties are simply described as lines, bars, circles, and rectangles at given positions, having identified luminance, chromaticity, or contrast values on a given background.

To underline how helpful it can be to pick the most appropriate coordinate system, consider the task of specifying the location of a point on the circumference of a regular spiral. The x, y, and z values in rectangular Cartesian coordinates will, of course, provide the desired information but they may

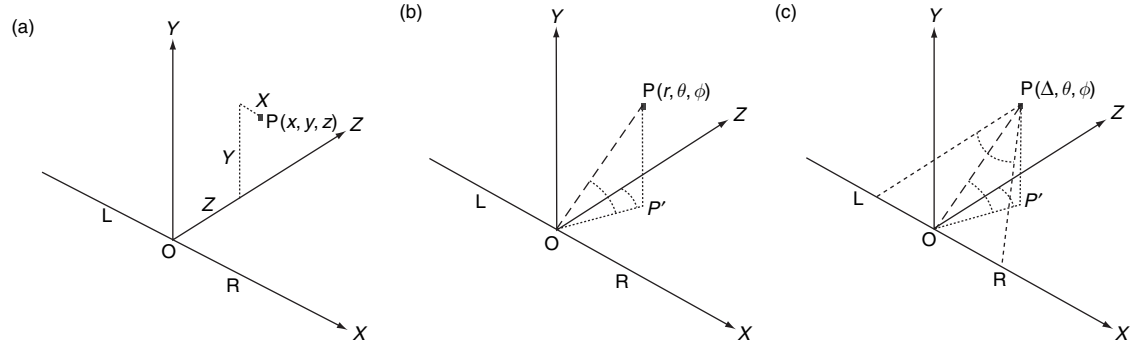

Figure 2 An example of transformation of stimulus specification in spatial vision. Information is fully conserved but rearranged to conform better to the anatomical or functional layout of the visual system. A point P is located in the upper right quadrant of the visual field. O is the location of the bisection of the interocular distance, and the head's mid-sagittal plane is aligned with the vertical. (a) Three-dimensional Cartesian coordinates: displacement of point from mid-sagittal plane of head (x), from the horizontal plane of regard (y), and along the z axis (z). (b) Here P is defined by the length of OP, that is, the radial distance r, and the orientation of line OP is defined by the two angles, θ between OP′ and OZ, describing laterality or azimuth, and ϕ between OP and OP′, describing elevation. (c) Coordinate r in the middle panel is replaced by the angle Δ between the lines from the right and left eyes to point P. In a given individual, because the distance RL is fixed, this angle is uniquely related to r. If the eyes are directed to a point at infinity on the z axis, the triangular coordinates of the point P in the binocular visual field yield an anatomically meaningful representation, binocular disparity Δ, azimuth θ, and elevation ϕ.

be quite opaque. Instead, if the orientation of the axis, the pitch, and the radius of is circumscribing cylinder have been previously fixed, how much more directly related to the situation is it to state the number of steps up the spiral and the angle within the turn! The advantage of coordinates intrinsic to the actual structure rather than more generic ones like the Cartesian becomes even more evident in the case of regular changes in radius as in a wood screw.

1.01.5 The Experimental Problem: Efficient Specification of Stimulus Variables

Reduction to a manageable set of variables can take many forms, usually predicated by prior knowledge of the sorting that the visual system does on the incoming signals. For example, when light or chromaticity are studied, pattern and shape variables are subsidiary, and vice versa. But it is surprising to recognize just how big the task is to specify the stimulus in even a narrowly defined experiment. Take the case in which a single gray Gabor patch is employed to probe a visual function. Its center location in the visual field has a distance from the eye and two angular coordinates. The underlying grating has orientation, mean light level ($cd\,m^{-2}$), amplitude, spatial frequency, and phase. Its modulating Gaussian envelope has standard deviation in two dimensions. It is a huge parameter space even though just a single basic pattern is employed to map the sensitivity profile of the human observer or perhaps a neuronal element (Figure 3).

Occasionally, more radical transformations in the spatial domain are encountered, which at their best involve no loss of information, that is, are fully reversible, yet produce an entirely different depiction of the world of visual stimuli than the pattern of light (and color) distributed before us in three-dimensional space as ordinarily regarded. A popular example is the Fourier transformation, which was borrowed from optics and holography. It is just one example of what are called kernel functions, in which the point-by-point energy distribution is sifted through, or convoluted with, a complete set of basis functions, covering space in an altogether different manner, in this particular case sinusoidal gratings in the full range of spatial frequencies. It results in a distribution providing the amplitudes and phases of all the gratings which, were super-imposed, would reconstruct the original world. It might be mentioned parenthetically that the widely utilized power spectrum is an incomplete description of the visual world because it contains no information on spatial phase.

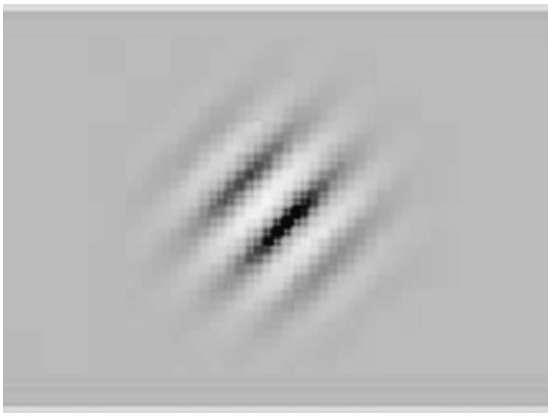

Figure 3 The Gabor patch is a popular stimulus used in vision research, yet needs a surprisingly large number of parameters for its specification. Even in the simple situation when it is black and white and shown in a plane perpendicular to the line of sight (1) the location of its center has three coordinates; (2) the underlying grating has orientation, amplitude, spatial frequency, and phase; (3) the Gaussian envelope has standard deviation in two directions unless it is circular; and (4) the background has luminance measured in $cd\,m^{-2}$. To these may have to be added the orientation of the display plane if it is not normal to the line of sight and, should color be of concern, chromaticity values of the pattern and background. As with all stimulus patterns, using Gabor patches in place of other alternatives implies the premise that this particular template has a singular value as a probe.

In principle, the manner of representation should not matter as long as certain safeguards are obeyed, particularly that it is complete and that it allows the full reconstruction of the original. However, once nonlinearities enter, the basis functions with which the object scene is analyzed need to be matched to the operations that are being performed. For example, if the retina subjects the incoming light to a center/surround filtering, and that operation is nonlinear, analysis by other means, say a set of elongated Gabor functions, will yield results that no longer allow predictions of the response to other kinds of stimuli.

This is not a trivial issue, because the essence of research into sensory processing is not just to report on a single experiment, no matter how rigorous the methodology and clean-cut the result. For exploring details of connectivity and cellular mechanisms, such as mapping of receptive fields of individual neural units, a limited test set, of course, can still be of value. But, in

principle, the aim is to predict how the visual apparatus and the whole organism will behave in more general situations, extrapolating from the ones tested in the laboratory. In the beginning, most of the research proceeded using stimuli that have firm footing in physics – white or monochromatic light and patterns based on classical geometry. However, as our understanding increased, stimuli were employed whose properties accommodate more sophisticated rules such as a logarithmic rather than linear progression in the light levels, or patterns that hug the well-documented spatial profiles of the neural stage being investigated, for example, circular difference of Gaussians in the retina, and bars and edges in the primary visual cortex.

However, there are widely expressed concerns that such stimuli, which include also random dot kinematograms and stereograms, are still too artificial and may not fully reveal the systems' performance under natural conditions. Exposing the visual system to natural scenes, for the purposes of analyzing it, may indeed reveal responses that were not predictable from those to simpler, more generic stimuli. But, while extending the range this does not solve the question of generalization from a particular class of stimuli to other, less predicable, ones.

1.01.6 Information Theory and Prior Probability

If the mission of vision science is to study the way the system gathers information about the environment – preparatory to its utilization for the organism's responses or storage for comparison with later input – it should not surprise that the movement launched under the banner of information theory was eagerly embraced. As famously formulated by Shannon, the unit of information, the bit, is the yes or no, or 0 or 1, binary answer to a single question. To make calculations for multiple events easier, they are performed in the realm of logarithms in which association rules are additive rather than multiplicative, so that the answer to two questions gives twice the information. Shannon went on to calculate the reduction of uncertainty, that is, the information gained, for the specification of a single letter of the English alphabet, which is $\log_2(26) = 4.7$ bits. Many areas of communication engineering gained clarity and precision by having apparently intractable situations laid out in such a lucid fashion. In particular, cost-effectiveness of various ways of communication could be compared and optimization achieved by minimizing duplication, technically called redundancy. Information is passed along channels usually after having been subjected to reexpression in a different form, that is, recoded. Concepts such as channel capacity and coding efficiency were developed. The analogy with what takes place in the passage from light reaching the retina to nerve impulses sent into the brain is so obvious that it would have been a dereliction of duty to neglect this new branch of scholarship. Information theory in its mathematical form can be used wherever data are adequately characterized and numerically presented, and this holds in many situations in vision science. Pixels, coding algorithms, and redundancy rules can be defined on the basis of the laws of optical physics as well as the structure of the eye's optics and the functional modules of the retina.

Looked at more closely, however, information theory contains some complexities, tackled right at the outset by Shannon. Though there are 26 letters in the alphabet, they do not occur equally often, so that more information is gained (or uncertainty diminished) when a q comes up than an e. This is taken into account by weighting each letter according to its frequency; as formally defined in Shannon's theory, the information content of an event depends on the set of prior probabilities of the elements of the ensemble. Thus the information gained when a letter of the alphabet is revealed depends on the frequency of its occurrence and this obviously will depend on the kind of text; similarly, the information content of being shown a particular word will depend on prior familiarity with the subject being treated.

Numerical specification of information transfer requires knowledge of the set of prior probabilities associated with the particular circumstances. It follows that the application of this approach will be successful (i.e., helpful in illuminating the operation of the visual system) to the degree that the situation allows quantitative expression about the elements of the ensemble and of their prior probabilities. Channel capacity, coding efficiency, and other such concepts are more meaningful when they involve readily quantifiable stimulus sets and output measurements, for example, impulses in a nerve fiber or an observer's yes and no responses in a psychophysical trial, than when a decision concerns, say, the identification of a face.

Prior probabilities also enter in the deployment of Bayesian inference, a brand of statistics that is being resurrected following years of neglect. In orthodox

statistics one estimates the probability that an encountered event might have arisen from one particular model. For example, how often would one get one's result under a null hypothesis, that is, that the operation in the test situation is indistinguishable from that in control situations? In Bayesian statistics this process is inverted: one tries to estimate the most likely of a range of models to give rise to the particular event, and for this purpose it is necessary to weight each model with its prior probability. Where this knowledge is available, Bayesian statistics is a powerful tool and to be preferred over the classical approach. But, where not, its point is missed.

This formulaic layout of both information theory and Bayesian statistics exposes the fundamental difficulty of studying perception via the inverse method, that is, inferring the stimulus from the givens of the percept. The state of the organism at any one time is compatible with (i.e., could have arisen from) a range of possible stimulus conditions, and to narrow these down one needs an idea of how likely each of them might be. An observer sees a set of black and white stripes; did they originate from:

1. the belly of a Bengal tiger?
2. the flank of a zebra?
3. the tail of a skunk? or
4. a Gabor patch shown on a monitor in an experimental setup?

The answer and the kind of response (fright, wonder, turning away, pressing the left button on a computer mouse) will depend on the context or, to use the technical phrase, the prior probability. At most times the direct (defined stimulus → observed response) research approach is preferred over the inferential (measured response → likely stimulus), but in some scientific enterprises, epidemiology for example, such a choice is not available.

Any benefits to our understanding of visual science from these modern approaches still lie in the future. But even if they turn out to be slim, they will have had the salutary effect of making us realize how much the traditional way of studying a sensory system, the one employing stimuli conceived in physics or derived from previous knowledge of the system's operation, needs to be supplemented. It has served well but its limitations are becoming more apparent as it is being recognized how far from invariant the apparatus is: properties change depending on its previous history and concurrent inputs. There are extensive interconnections within each neural stage of the visual stream, as well as between the stages in the form of feedback and top-down pathways. As a consequence, in the alert, behaving organism the state of the circuit in which it is imbedded is as much a factor in the response of a neural element in the central visual system as the immediate incoming signal from the eye. In the road ahead, approaches will be needed that transcend the time-honored simple input → output ones that have enabled the construction of the rich knowledge base of the visual sense so eloquently related in the chapters of the present volume.

Glossary

monophyletic A group of organisms or traits arising from a single, inferred common ancestor or ancestral trait.

polyphyletic A trait which evolved independently in different organisms.

phylogeny The evolutionary relatedness amongst organisms.

photoreceptor Specialized type of neuron found in the eye capable of converting light into a neural signal.

phototransduction The process of converting light energy into neural energy.

1.02.1 Introduction

Sunlight provides energy essential for all life on earth and is a profoundly important selective force, which has driven the evolution of processes that harvest the sun's energy. However, equally important, light is the premier source of information for many species driving evolution of light-sensing organs, including eyes that harvest information. So since the beginning of biological evolution on our planet over 5 billion years ago, sunlight has both fueled and informed life. Light, and the light/dark cycle from the rotating earth may be second only to sex as the most important selective force that has acted on biological organisms. One of the most remarkable evolutionary consequences of sunlight has been the evolution of mechanisms that convert photons into signals useful to organisms. Understanding the evolutionary history of eyes, however, has been vexed, because their fossil remains give limited information about their function and origins. So in understanding the genetic, biochemical, and structural remnants of eye evolution, Ernst Mayr's dictum: "evolution is an affair of phenotypes" provides a guide. This is particularly true when trying to uncover commonalities amongst the varieties of eyes and mechanisms to convert photons into energy useful to their owners.

How did eyes evolve? Darwin knew that eyes offered a special challenge to evolutionary thinking stating "... that the eye ... could have been formed by natural selection seems, I freely confess, absurd in the highest possible degree" (Darwin, C., 1859). This is the most frequently cited quote of Darwin about eyes but he also wrote: "Reason tells me, that if

numerous gradations from a simple and imperfect eye to one complex and perfect can be shown to exist, each grade being useful to its possessor, as is certainly the case; if further, the eye ever varies and the variations be inherited, as is likewise certainly the case; and if such variations should be useful to any animal under changing conditions of life, then the difficulty of believing that a perfect and complex eye could be formed by natural selection, though insuperable by our imagination, should not be considered as subversive of the theory" (Darwin, C., 1859). Though understanding eye evolution challenges the imagination, several new findings have changed our fundamental understanding about the origins of eyes.

New insights about eye evolution at the molecular level are the discovery of clusters of genes implicated in eye development that are conserved in eyes across large phylogenetic divides. Moreover, it is now clear now that vertebrate genomes contain nearly twice as many genes encoding light-transducing opsin proteins as previously known. But most importantly, physiologists have identified two fundamentally different kinds of photodetection systems in single organisms. In fact, within the eye of vertebrates, there are now known to be two fundamentally different kinds of phototransduction cascades, apparently collaborating to interpret information from light signals. Taken together, these new insights provide a much clearer story about how and how often eyes arose during evolution.

1.02.2 Structural and Functional Adaptations in Eyes

1.02.2.1 General Constraints

Walls G. L. (1942), in his monumental book provided remarkable insights about the many features of the vertebrate eye with detailed drawings showing the range and variety of vertebrate eye phenotypic characteristics. The variety of adaptations in eyes produced by selective pressures for vision in different habitats is truly astonishing. But eye structures depend critically on the physical properties of light which sets limits on how light can be collected and focused. For example, eyes have evolved to be sensitive to only a narrow range of wavelengths, relative to the broad spectrum of energy produced by sunlight (see Figure 1). This is probably because early evolution occurred in water that reduces light dramatically as a function of wavelength (Fernald, R. D., 1988). Selection favored biochemical mechanisms sensitive in this limited range of wavelengths and set the sensitivity for subsequent evolution of light detection. Many species have long lived on land where they are exposed to the broader spectrum of electromagnetic radiation from the sun, yet most animal eyes transduce light only within the original narrow band dictated by water. Some insects and species of fish and birds later evolved additional receptor types for ultraviolet light (e.g., Viltala, J. *et al.*, 1995) in response to the terrestrial

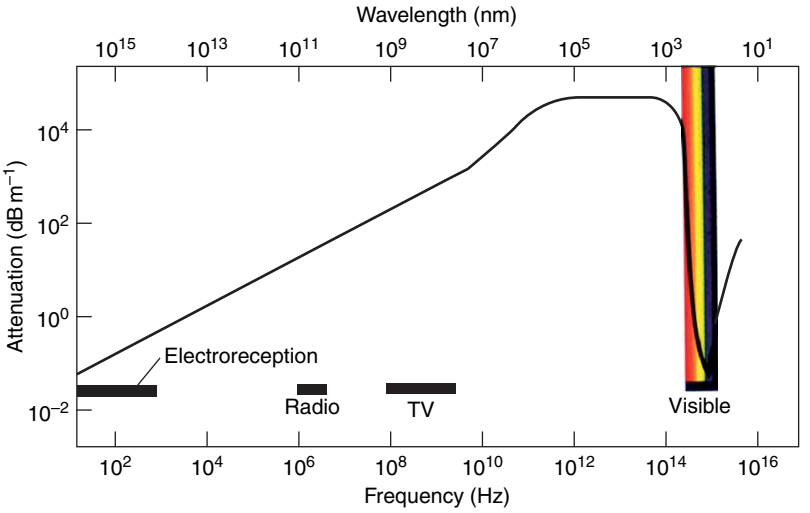

Figure 1 The attenuation (decibels per meter) of electromagnetic (EM) radiation by water as a function of wavelength (nm; top) and frequency (Hz; bottom). Significant amounts of EM radiation cannot pass through water except in two ranges: under 10^3 Hz and from 10^{14} to 10^{15} Hz. Animals have exploited these two ranges for communication: weakly electric fish communicate using the low range and visible light used by all eyes is in the upper range. Adapted from Fernald, R. D. 1988. Aquatic Adaptations in Fish Eyes. In: Sensory Biology of Aquatic Animals (*eds.* J. Atema, R. R. Fay, A. N. Popper, and W. N. Tavolga), pp. 185–208. Springer.

environment. Thus the narrow range of wavelength sensitivity is a residual reflection of our aquatic origins and illustrates how early evolutionary solutions persist in the evolved organs.

Among animals, of the ~33 animal phyla, about one-third have no specialized light-detecting organ, one-third have light sensitive organs, and the remaining third have eyes (Land, M. F. and Nilsson, D. E., 2002). Image-forming eyes have appeared in six of the 33 extant metazoan phyla (Cnidaria, Mollusca, Annelida, Onychophora, Arthropoda, and Chordata), and these six contribute about 96% of the known species alive today (Land, M. F. and Fernald, R. D., 1992), suggesting that eyes contribute to evolutionary success. Existing eyes range in size from a fraction of a millimeter to tens of centimeters in diameter and the range of types and locations suggests that they can evolve relatively easily (see below).

1.02.2.2 Optical Constraints

Only three types of image forming optical systems have evolved in eyes (Figure 2): images formed by shadows, by refraction (e.g., lens and/or cornea), or by reflection as first systematically studied by Land M. F. (1981). Since physical laws governing light fundamentally limit how an eye can function, similar structures have evolved in distinctly unrelated animals such as fishes and cephalopods. The chambered or camera eyes in these two lineages are very similar in a large number of details, despite the fact that their owners are phylogenetically quite distant (Packard, A., 1972; Fernald, R. D., 2006). Both evolved spherical lenses to achieve sufficient refractive power for focusing light underwater, but the inverted retinal layers of fishes and all vertebrates are distinctly different from the noninverted, somewhat simpler retinae of cephalopods. Moreover, each group uses a different family of opsin molecules and different transduction cascades to process photons. Macroscopically, these eye types and the animals bearing them are not homologous, even though there are striking similarities and even some homologies at the molecular and developmental levels. This seeming contradiction lies at the heart of understanding eye evolution.

The greatest variety of eyes has been found in invertebrates, which have both camera eyes (e.g., cephalopods) and compound eyes (e.g., *Drosophila*). Moreover, invertebrates also have the greatest variety in eye number and location in particular species. Whereas vertebrates have paired, chambered, lensed eyes on the head, invertebrates species may have multiple, nonpaired eyes and eyes in remarkable locations. For example, certain butterflies have light-detecting organs located such that darkness signals successful copulation (Arikawa, K. *et al.*, 1996a; 1996b). In addition, Nordström K. *et al.* (2003) described a visual system in the planula of a box

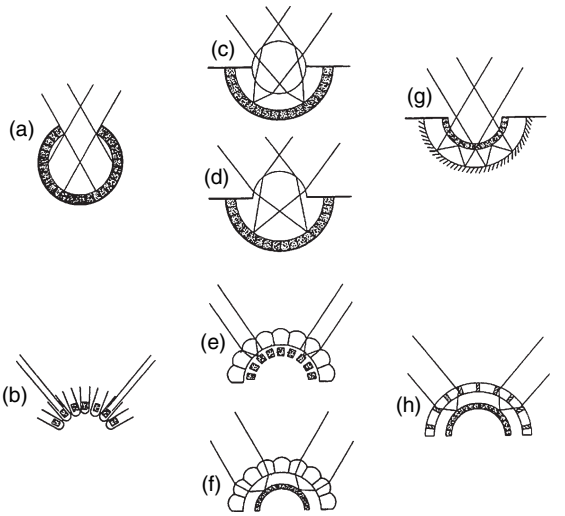

Figure 2 Major eye optical types found in animals. Chambered eyes (top: (a), (c), (d), and (g)) and compound eyes (bottom: (b), (e), (f), and (h)). Eyes form images using shadows (a, b), refraction (c–f), and reflection (g, h). The simple pit eye (a) led to the lensed eyes in fish and cephalopods (c) and terrestrial animals (d). Scallop eyes (g) are chambered but use concave mirror optics to produce an image. The simplest compound eye (b) found in bivalve molluscs led to the apposition compound eye (e) found in bees and crabs, the refracting superposition compound eye (f) of moths and krill and the reflecting superposition eye (h) found in decapod shrimps and lobsters. Adapted from Land, M. F. and Nilsson, D. E. 2002. Animal Eyes. Oxford University Press.

jellyfish *Tripedalia cystophora*, with eyecups directly connected to motor cilium meaning no nervous system processes visual information, making the eyes a complete sensory–motor system.

There is great variation in the capacities of eyes depending ultimately on their structure. For example, resolution of an image, as measured in degrees subtended differs by about 13-fold among vertebrates and even more between vertebrates and invertebrates. Eagles have the greatest acuity that is around 10 000-fold greater than that found in planaria (Land, M. F. and Nilsson, D. E., 2002). Similarly, a comparison of relative sensitivities among vertebrates reveals a range of 4×10^5 between highly sensitive deep sea animal vision and human foveal vision (Land, M. F. and Nilsson, D. E., 2002).

Another remarkable adaptation is differential wavelength sensitivity of photoreceptor types producing what we call hue or color discrimination. The selective pressures for evolution of wavelength discrimination appear to have been quite pervasive. Probably, the added value of better contrast detection, which increases the likelihood of recognizing food, mates, and predators, would have been enhanced with chromatic information (e.g., Nagel, M. G. and Osorio, D., 1993; Osorio, D. and Vorobyev, M., 1996). Indeed, recent work comparing eight primate taxa suggests that trichromatic vision evolved where leaf consumption was critical (Lucas, P. W. *et al.*, 2003). In support of this idea, many species of diurnal reptiles and birds have colored retinal filters, made of oil droplets, which appear to have evolved to increase the number of colors that can be discriminated, suggesting selective pressure for improved color vision (Vorobyev, M., 2003).

1.02.2.3 Lenses: Multiple Protein Types and Gene Sharing

Eyes collect light through an aperture, and focus it with a lens onto photoreceptor cells specialized to convert photons into neural signals. Some eyes exist without pupils and even without lenses (e.g., *Nautilus*), but eyes that evolved to give their owners a clear view of the environment over a short timescale do have lenses. Since lenses are constructed of tightly packed proteins, their evolutionary relationships might provide some insight into eye evolution.

In vertebrates, lenses are formed from modified epithelial cells which have high concentrations of soluble proteins, known as 'crystallins' because they are packed into arrays. In contrast, in most invertebrates, lens proteins are secreted by specialized cells in the eye. Interestingly, lenses of mitochondrial origin have been found in the two pairs of eyes of the parasite *Neoheterocotyle rhinobatidis* (Rohde, K. *et al.*, 1999). Despite very different cellular origins, to function optically lens proteins must be distributed to produce a radial gradient of refractive index that is low at the edge of the lens and high in the center (see Kroeger, R. H. H. *et al.*, 1999). An exact gradient of refractive index is essential for vision in animals living in water but such gradients are also found in lenses of terrestrial vertebrates and invertebrates. Perhaps most remarkably, cephalopods assemble their spherical lens from two distinct embryological sources, yet manage to produce the obligatory gradient of refractive index (Jagger, W. S. and Sands, P. J., 1999).

Until quite recently, the 10 or so crystallin proteins found in lenses were thought to be unique to lens tissue, presumed to have evolved for this function and formed a closely related phylogenetic family. Of the large number of crystallins, alpha and beta–gamma crystallins are indeed specialized lens proteins in vertebrates, related to heat shock protein and schistosome egg antigen, respectively. However, the many remaining vertebrate lens proteins are a not conserved but rather are a diverse group, many of which are used as enzymes elsewhere in the body. Surprisingly, most of these taxon-specific lens proteins are actually products of the same genes as the enzymes, a double use that has been termed 'gene sharing' by Wistow G. (1993a; 1993b). For example, a crystallin protein in the duck lens was shown to be similar to a metabolic enzyme, argininosuccinate lyase. Both the lens protein and the metabolic enzyme are encoded by the same gene, not from duplicated genes and such sharing might be a prelude to gene duplication. Such molecular opportunism is so effective that it has also occurred both in cephalopods (Tomarev, S. I. and Zinovieva, R. D., 1988) and in *Drosophila* (Janssens, H. and Gehring, W. J., 1999). One possibility is that since lenses need the production of a relatively large amount of protein, genes that have been successfully upregulated in other tissues might be preferentially selected.

Remarkably, the brittlestar (*Ophiocoma wendtii*), form crystal lenses as a part of their skeletal armor from calcite crystals. The crystals, oriented to bring light onto the photoreceptive surfaces in the body, focus the light much as corrective lenses might and effectively concentrate the light by ~50 times (Aizenberg, J. *et al.*, 2001).

The common cellular strategy of assembling lenses from diverse, phylogenetically unrelated proteins seems to be a convergent evolutionary solution that has occurred in many vertebrates independently. The exquisite gradient of the refractive index, which evolved in vertebrates and invertebrates alike resulted because it is the only way known to make an optically useful lens. What remains unknown is how such diverse protein species are assembled and folded to preserve key properties of transparency and refractive index gradient along the axis of the lens. The challenge for understanding lens development is to identify mechanisms responsible for organizing diverse proteins into a functioning lens. However, since lenses appear to have evolved along independent lines, their phylogenetic relationships do not provide a useful window into eye evolution.

1.02.2.4 Capturing Photons: The Opsin/Retinal Solution

Transducing light is the essential function of visual systems and an ancient molecule, opsin, in association with other key players has a long evolutionary history. Vertebrate opsins, also called visual pigments, appeared before eyes (Land, M. F. and Fernald, R. D., 1992) and evolved along at least seven lines, diverging from an ancestral type, before teleost fish diverged from other vertebrates (e.g., Hisatomi, O. *et al*, 1994) and indeed before deuterostomes split from the protostomes (Terakita, A., 2005). This suggests that a common ancestor had multiple opsin genes, which has been recently confirmed (see below). The exact sequence along which opsins evolved is still open to interpretation (e.g., Okano, H. *et al*., 1992), but it is clear that they evolved in parallel.

Opsins are seven transmembrane proteins (30–50 kDa) that associate with a nonprotein moiety, the chromophore, retinal. Among the ~1000 opsin forms that have been described to date, the phylogenetic differences among the seven major groups correspond to specific functional classifications (Figure 3). These classes differ in several ways but perhaps most importantly in their transduction via different G proteins. For example, although both vertebrate and invertebrate photosensitive opsin receptors are G-coupled (e.g., heterotrimeric guanine nucleotide-binding protein-coupled), and both use 11-*cis*-retinal or a close variant as their chromophore, vertebrate rod-and-cone opsins signal through photoreceptor-specific, G proteins called transducins. In contrast, invertebrate opsins signal through the G_q family of G proteins. In addition, photic responses are terminated differently. In vertebrates, excitation is followed by a combination of phosphorylation of the excited opsin, the binding of arrestin proteins which is then followed by regeneration of the active chromophore form needed for photosensitivity (Figure 4). The process in invertebrates is quite different where the G protein is inactivated by its target, phospholipase C.

Opsin function is very well understood (e.g., Menon, S. T. *et al*., 2001) and the adaptive radiation of pigment types due to natural selection for particular wavelength responses has been described for some special cases (e.g., east African cichlids, Sugawara, T. *et al*., 2002; squirrelfish, Yokoyama, S. and Takenaka, N., 2004). Moreover, the evolutionary relationships among rhodopsin molecules is well-known and some

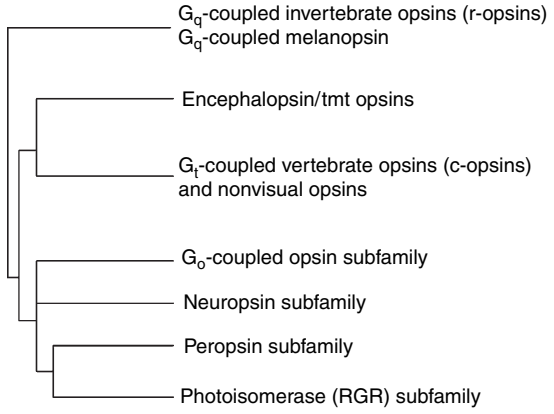

Figure 3 A simplified schematic molecular phylogenetic tree inferred by the neighbor-joining method showing the seven known opsin subfamilies. RGR, retinal G-protein-coupled receptor; TMT, teleost multiple tissue. Adapted from Terakita, A. 2005. The opsins. Genome Biol. 6, 213.

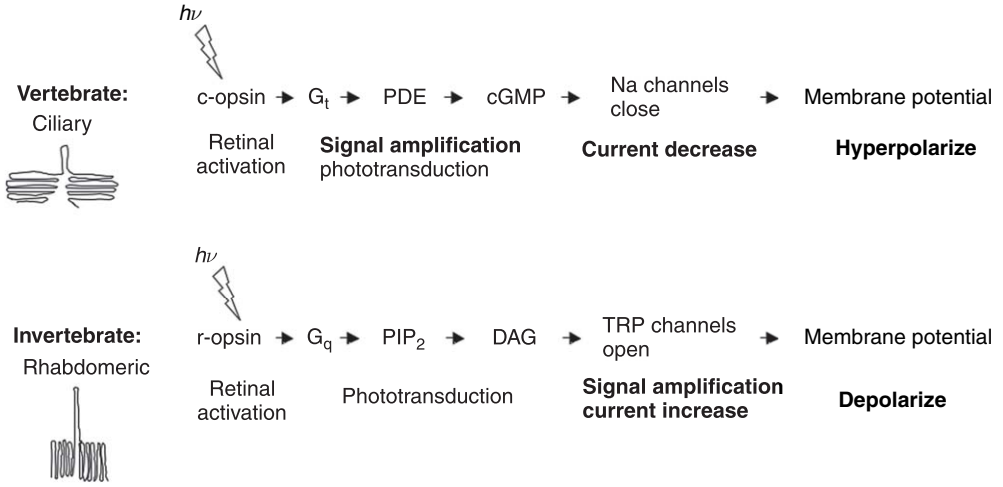

Figure 4 Schematic illustration showing the key differences between a simplified representation of (top) canonical vertebrate ciliary phototransduction and (bottom) invertebrate rhabdomeric phototransduction where $h\nu$ represents incident photon energy. The two different opsin types (c-opsin and r-opsin) are contained in distinctly different membrane types, ciliary, and rhabdomeric. The opsins are coupled to different families of G proteins that act via different types of transduction cascades. Amplification occurs during phototransduction in ciliary receptors and during channel opening in rhabdomeric receptors. These cascades produce signals of different sign. cGMP, cyclic guanosylmophosphate; DAG, diacylglycerol; G_q, guanine nucleotide-binding protein α15; G_t, transducin; PDE, phosphodiesterase; PIP_2, phosphatidylinositol-4,5-biphosphate.

of this is based on understanding the interaction between retinal and opsin (Marsh, L. and Griffiths, C. S., 2005). However, there has been considerable variance in spectral sensitivities that likely resulted from specific selective advantages for one solution over another. Detailed comparisons between terrestrial vertebrates and insects, for example, reveal that there are not unique solutions to encoding both spatial and spectral information. Mammals and bees use long-wavelength receptors for luminance and color vision while flies and birds have evolved separate sets of photoreceptors for the two purposes (Osorio, D. and Vorobyev, M., 2005).

Primate photopigments also offer examples of relatively recent evolutionary change in these important molecules. For example, Old World monkeys, apes, and humans have trichromatic vision, while New World monkeys are polymorphic, having dichromatic or trichromatic color vision (Jacobs, G. H., 1996). In this context, *Homo sapiens* may be unique in the polymorphism found in our color vision system (e.g., Neitz, M. *et al*, 1996). The variance in number and kinds of photopigments in the human retina might reflect the reduced selective pressure on color vision. The subtlety of selective pressures on chromatic detection is clear in many species. For example, in the bluefin killifish, the relative abundance of cone types depends on whether the animals live in springs or swamps (Fuller, R. C. *et al*., 2003). The novel differential spectral sensitivity in these populations is produced epigenetically through differential expression of cone classes in the retina, rather than via modification of the spectral tuning of opsin molecules, showing that there are different ways to achieve different kinds of chromatic sensitivity.

Another kind of mechanism modifying wavelength sensitivity in cone photoreceptors that depends on life history changes has been described in Pacific salmon (*Oncorhynchus gorbuscha*) and in winter flounder (*Pseudopleuronectes americanus*). As salmon grow and move from being planctivores living in surface waters where ultraviolet (UV) light is abundant to fish-eating predators in deeper waters where blue-green light prevails, they remodel their UV-sensitive cones with insertion of an opsin that is tuned to blue wavelengths (Cheng, C. L. and Flamarique, I. N., 2004). A similar mechanism has been previously reported in winter flounder (*Pseudopleuronectes americanus*) in which a single opsin type in juveniles, located in hexagonally arranged single cones is replaced by three different opsin types in photoreceptors arranged in a square array after the animal has metamorphosed into an adult (Evans, B. I. and Fernald, R. D., 1993; Evans, B. I. *et al*., 1993).

These examples and abundant others show that animals have evolved eyes with resolution, sensitivity

and wavelength detection to match their needs. Specifically, wavelength sensitivity can change with such life history changes and be quite different in closely related species. The best understood visual transduction mechanisms are those used for the main visual input in both vertebrates and invertebrates. The role of the five other opsin families and their mechanisms of visual transduction are beginning to be understood although a great deal remains mysterious.

1.02.3 Evolutionary Origins

1.02.3.1 Developmental Evidence about Eye Evolution

Logically, eyes might be monophyletic, having evolved from a single progenitor, or polyphyletic, having arisen more than once during evolution. Once it was understood that opsin played a role in phototransduction in all eyes that had been investigated, eyes were thought to have a single, monophyletic origin. The notion was that a phylogenetic tree of one important functional protein, opsin would link all eye types together. However, Salvini-Plawen L. V. and Mayr E. (1977) took a completely different perspective and compared overall structure, photoreceptor types, developmental origins of eye tissue, position of receptor axons, and other anatomical markers among eyes using existing fauna. Based on this analysis, they came to the conclusion that eyes evolved not once but at least 40 different times, and possibly many more (reviewed in Land, M. F. and Fernald, R. D., 1992). This 'multiple-origins' hypothesis, based on morphological evidence was unchallenged for 20 years until results comparing developmental pathways at the molecular level revealed a major surprise. Specifically, Gehrig and co-workers showed that *pax6* could induce ectopic eyes in fruit flies, leading them to dub this a 'master regulatory gene' (Halder, G. *et al*, 1995). Based on these results, Gehring W. J. and Ikeo K. (1999) proposed that because a single, well-conserved gene, *pax6*, could initiate eye construction in mice and flies, eyes must have arisen from a single ancestor. Did eyes appear many times in the course of evolution making them polyphyletic, as claimed by Salvini-Plawen and Mayr based on phenotype or have all eyes 'descended' directly from a common, primitive form, making them monophyletic, as claimed by Gehring *et al.* based on genes controlling development? Since this original debate erupted, there have been several important discoveries showing that eyes must have arisen more than once and, that we carry the evidence in our own eyes!

By the Cambrian period (570–500 million years ago), eyes were present in the form of very simple eyecups, useful for detecting light but not for processing directional information. Although the causes are unknown, explosive speciation, or the 'Big Bang' of animal evolution happened during the Cambrian (Conway-Morris, S., 1998). Existing eye types improved radically, coincident with the appearance of carnivory and predation. The evolution of ocular structures has proceeded in two stages (see Figure 2; Land, M. F. and Fernald, R. D., 1992). First was the production of simple eye spots which are found in nearly all the major animal groups and contain a small number of receptors in an open cup of screening pigment (Land, M. F. and Fernald, R. D., 1992). This kind of detector cannot play a role in recognizing patterns but rather for distinguishing light from dark. The second stage in eye evolution is the addition of an optical system that can produce an image. As noted above, image-forming eyes occur in 96% of known species distributed among the six phyla. Although there are basically only three methods of forming an image, among the known eye types are at least 11 distinct optical systems producing images, the most recently described is a telephoto lens, identified in the chameleon in 1995. Indeed, six of the optical systems have only been discovered in the past 25 years.

Since camera-type eyes are demonstrably superior in several respects (Nilsson, D. E., 1989), why do not all animals have them? Camera-type eyes require big heads and bodies to hold them, which likely restricted the number of animals that have followed this evolutionary path. Also, it is probable that, having evolved one eye type, conversion to another type requires intermediate stages that are much worse or useless when compared with the existing design. This would make a switch essentially lethal to animals that depend on seeing. Although this argument makes sense intuitively, some existing cases of novel optical combinations suggest this is probably not the whole story.

For teaching purposes, textbooks tend to group animal eyes into two groups, the camera-type or 'simple' eyes and the compound eyes, which does reflect a real and fundamental difference in visual systems. However, such a dichotomy conceals a remarkable diversity of optical systems subsumed under each heading.

For example, Nilsson D. E. and Modlin R. (1994) described a mysid shrimp (*Dioptromysis paucispinous*) that has a combined simple and compound eye: partly compound with multiple facets exactly like the eye of an insect, and partly simple with a single lens focusing an image on a sheet of receptors like that of a human. These shrimp are about 5 mm long with nearly spherical eyes at the ends of stalks. In addition to the facets (~800–900) there is a single giant facet facing the shrimp's tail, which the shrimp frequently rotates forward probably to get a better look at something since that facet has ~5 times the acuity (but much lower sensitivity) than the rest of the eye. It is as if the shrimp were carrying a pair of binoculars for the occasional detailed look at something ahead of it. The discovery that simple and compound eye types can be found in a single animal raises the question of how a developmental program could produce this outcome.

1.02.3.2 Developmental Evidence about Eye Evolution

Classical experimentation directed at understanding ocular development focused on vertebrate eyes, a specialized extension of the brain. Experimental models were primarily limited to mice and chicks due to their extensive prior exploitation as model organisms. The beautiful images available today make the often subtle but distinctive morphological changes during eye development seem much more obvious than they were when first observed since it is now possible, with scanning electron microscopy and sophisticated methods of controlling the state of tissue development, to watch unfolding of the production of an eye.

Eyes develop from the prospective forebrain, beginning in the eyefields, which are made up of cells of the anterior neural plate. As the prosencephalon grows, this region moves forward until the optic groove forms, and the neuroectoderm of the groove locally contacts the surface ectoderm, inducing the lens placode. As the placode invaginates to form the lens vesicle, the optic vesicle forms the bilayered optic cup, which ultimately becomes the eye. The interaction between the optic vesicle and the lens placode was identified as the 'organizer of the lens' by Spemann H. (1924). The presumptive lens arises from the lens placode, a thickening of the ectoderm in contact with the optic vesicle. Coincident with this change is the onset of expression of proteins that will form the lens. Other structures of the eye are formed by large- and small-scale tissue movements, caused and accompanied by the expression of tissue-specific genes at that site. The cornea arises from the surface ectoderm over the lens and from migrating mesenchyme derived from the neural crest. Many of the original observations about the role of specific tissue bits in these processes resulted from exquisite embryonic manipulations related to transplantation experiments. For example, Nieuwkoop P. D. (1963) identified, among other things, the source tissue essential for the induction of eye production.

With macroscopic changes described, the next challenge has been to synthesize the phenomenological, macroscopic morphological observations with molecular explanations of eye development and understand what this tells us about evolution. The morphological process of eye development has been viewed as a set of steps toward a final tissue arrangement but underlying this apparently straightforward sequence of large-scale events are distributions of gene expression with substantial overlap in both time and space. Gene expression is closely regulated, and we know that specific genes and gene products are used repeatedly, making the causal relationships among the players difficult to conceptualize. Nonetheless, progress in characterizing the genes responsible for particular steps in eye development has been reasonably rapid, as shown in several recent reviews (Harland, R., 2000; Chow, R. L. and Lang, R. A., 2001; Graw, J., 2003). Functions for at least 15 transcription factors and several signaling molecules have been described in human and mice eyes, based on developmental disorders and/or molecular manipulations (e.g., Graw, J., 2003). As with other molecular actors, the transcription factors and signaling molecules are expressed during ocular development are also essential for normal development in a wide range of other tissues. This suggests that a particular combination of expression patterns and their timing is important for the proper functioning of these genes in eye development.

It is known that the paired box gene 6 (*pax6*), a member of the family of genes that encode transcription factors with a homeodomain and a paired domain, appears to be important in eye formation across many species. The remarkable demonstration that *pax6* can induce eyes where they should not be ('ectopic') in *Drosophila* (Halder, G. *et al.*, 1995), and similar subsequent demonstration in vertebrates (Chow, R. L. *et al.*, 1999), led to the suggestion that there might be 'master control genes' responsible for

development and differentiation of ocular tissue in many species. Subsequent work has shown, however, that 'master control gene' is a misnomer since a suite of genes are required, collectively, to initiate eye development, all of which are essential. Moreover, as noted above, the genes in question actually have dynamic spatial and temporal expression during many stages of eye development, in addition to expression for essential purposes in other tissues and organs in the brain and elsewhere. Nonetheless, it is remarkable that some of the same genes appear in the context of eye development, despite great evolutionary distance among the owners of the eyes. How this might have occurred is discussed below.

For *Drosophila* eyes, the story has become considerably more complex. It seems that not one but a collection of seven genes, encoding transcription factors and two signaling molecules collaborate to make eyes (reviewed in Kumar, J. P., 2001). These nuclear factors (*eyeless* (*ey*), *twin of eyeless* (*toy*) – both of which are *pax6* homologs, *sine oculus* (*so*), *eyes absent* (*eya*), *dachshund* (*dac*), *eye gone* (*eyg*), and *optix*) and signaling systems, including the Notch and receptor tyrosine kinase pathways, act via a complex regulatory network that is reasonably well understood (see Kumar, J. P., 2001; Figure 1). The master gene hypothesis is not supported, because deletion of any of these genes causes loss or radical reduction in the *Drosophila* compound eye and, surprisingly, any gene except *sine oculus,* in collaboration with certain signaling molecules, can cause ectopic expression of an eye in a limited set of imaginal disks. This means that the whole troupe is needed to produce a reasonable eye. Why this might be so is suggested by recent work showing that the *eya* gene products are phosphatases, the first case in which a transcription factor can itself dephosphorylate other proteins to fine tune gene expression (Li, X. *et al*., 2003). This elegant work demonstrated the details of interactions among *Six1*, *Dach*, and *Eya* in the formation of the kidney, muscle, and inner ear, as well as eyes, suggesting that this suite of genetically interacting proteins has been recruited repeatedly during evolution for organogenesis of different structures.

It is difficult to abandon the heuristic of hierarchical regulatory processes in development originally proposed by Lewis to characterize homeotic properties of bithorax and antennapedia genes but molecular analysis of eye development shows that this concept may not be useful. Instead, eye development appears to need new ways of thinking about how complex tissues are made and how such organs arose in evolution. The widespread and redundant activities of specific genes during ocular development (e.g., Chauhan, B. K. *et al*., 2002; Baumer, N. *et al*., 2003) suggest that hierarchies, if they exist, are unknown and the more likely scenario is the orchestrated activity of a suite of molecular actors.

As described above, the diversity of eyes confirms their dynamic evolutionary past. Explosive speciation, or the 'Big Bang' of animal evolution happened during the Cambrian (Conway-Morris, S., 1998), when existing eye types appear to have improved radically, coincident with the onset of carnivory and predation. Many selective forces were likely at work (Fernald, R. D., 2000), including perhaps the first instances where light enabled behavioral signals (Parker, A. R., 1998) so no predominant selective force can be claimed. The rapidity of eye evolution has always been a question, but, using a simulation, Nilsson D. E. and Pelger S. (1994) suggested that about 2000 sequential changes could produce a typical image-forming eye from a light sensitive patch. With reasonable estimates, this suggests that an eye could evolve in less than half a million years making the virtual explosion of eyes during the Cambrian seem quite reasonable (Land, M. F. and Nilsson, D. E., 2002). After the Cambrian, three phyla emerged: arthropods, mollusks, and chordates. Although these groups all use the opsin molecule to capture light, details of the structure and function of their eyes differ considerably.

One of the most interesting developmental differences among extant eyes is the embryonic origin of the different structures comparing the camera eyes in vertebrate and cephalopod eyes (summarized in Nilsson, D. E., 1996). Cephalopod eyes form from an epidermal placode through successive infoldings, whereas vertebrate eyes emerge from the neural plate and induce the overlying epidermis to form the lens as described above. It is also noteworthy that the cephalopod eyes lack a cornea, which is present in all vertebrates whether aquatic or not. In addition to the differences in embryonic origin, photoreceptor cells divide into either ciliary or microvillar structures to provide the membrane surface for the opsin molecule (Salvini-Plawen, L. V. and Mayr, E., 1977). Microvilli predominate in invertebrates, whereas vertebrate photoreceptors are ciliary. Physiological responses are also quite different, with the microvillous receptors of arthropods and mollusks depolarizing to light, and the ciliary receptors of vertebrates hyperpolarizing to light. In phototransduction, vertebrate photoreceptors exploit

cyclic guanosine 5′-monophosphate (GMP) as a second messenger system, while invertebrates use inositol trisphosphate (Fernald, R. D., 2000). And, even though opsin is the key molecule for detecting light, mechanisms for regeneration (e.g., reisomerization) of the chromophore/opsin system are dramatically different among phyla (Gonzalez-Fernandez, F., 2003).

1.02.3.3 Functional Evidence about Eye Evolution

Until recently, the photo detection systems we understood well were localized primarily to eyes and pineal glands and a few other sites in the body such as the skin. For each of these, a canonical opsin and related transduction cascade were known. Specifically, ciliary structures associated with specific G proteins are known from vertebrate eyes and microvilli associated with inositol phosphate signaling cascades are known from invertebrate eyes (see above). Then, in several laboratories, each of these phototransduction cascades was found in unexpected organisms. Arendt D. *et al.* (2004) found that the polychete ragworm (*Platynereis dumerilii*) in addition to the rhadomeric photoreceptors in its eyes, had ciliary photoreceptors in the brain. This group also showed that the typical types of opsins associated with each photoreceptor type were both expressed in the ragworm and localized only with that type (e.g., vertebrate c-opsin in the brain and invertebrate r-opsin in the eye). This means that the two main types of 'eyes' exist in a worm.

The idea that two kinds of photoreceptors might exist in an invertebrate was first suggested by the pioneering work of Gorman who, with co-workers showed physiological and morphological data suggesting both types of photoreceptors exist in a scallop, *Pecten irradians* (Gorman, A. L. F. and McReynolds, J. S., 1969; Gorman, A. L. F. and McReynolds, J. S., 1971). These investigators found depolarizing and hyperpolarizing responses to light stimuli from cells located in different layers of the scallop retina, with depolarizing potentials arising from the proximal layer and hyperpolarizing potentials form the distal layer. The investigators interpreted their data solely with respect to the various kinds of selective advantages each response type might have but did not consider the evolutionary implications though their data support the existence of the two canonical receptor types in one organism.

Somewhat earlier, in vertebrates, a parallel set of results appeared. A small population of intrinsically photosensitive retinal ganglion cells were been discovered that play key roles in the regulation of nonvisual photic responses. Surprisingly, these rely on melanopsin (see Figure 3), an opsin first identified in vertebrate melanophores, brain and eyes by Provencio I. *et al.* (1998). The melanopsin in the retina was found to underlie photosensitive ganglion cells discovered by Berson D. M. *et al.* (2002), shown to be required for normal light-induced circadian phase shifting (Panda, S. *et al.*, 2002) and yet could not function without the presence of normal rods and cones (Ruby, N. F. *et al.*, 2002). Taken together, this meant that signals from the photosensitive ganglion cells were being combined with those from rods and cones somewhere in the visual system.

Photosensitive ganglion cells were then thought to comprise a nonimage-forming system that can detect the presence or absence of light but not much more. Subsequent functional analyses showed that retinal melanopsin functions via a phototransduction cascade that resembles invertebrate opsins and, in another similarity to invertebrates has intrinsic photoisomerase activity (Panda, S. *et al.*, 2005; Qiu, X. *et al.*, 2005). Adding to the remarkable set of discoveries, melanopsin-expressing ganglion cells in the primate retina have been shown to signal color and radiance levels to the lateral geniculate nucleus (Dacey, D. M. *et al.*, 2005). So, not only do vertebrates carry a version of the invertebrate visual transduction system with them, but it is used in a variety of ways, including to provide information to the 'image-forming' visual system.

There are several remarkable conclusions to be drawn from this work. First, these findings show that at least two kinds of photoreception existed in the Urbilateria, before the split into three Bilateria branches at the Cambrian (Figure 5), and, importantly, each of these branches still carry versions of these two systems. It is noteworthy that cryptochromes, also discovered very recently (Cashmore, A. R. *et al.*, 1999) are another photoreceptive system that is not based on opsin, has no molecular amplification and is found in both plants and animals. To date, cryptochromes have been shown to play a role in circadian rhythms (Green, B. C., 2004) and control of the iris muscle in birds (Tu, D. D. *et al.*, 2004) as well as many functions in plants.

Second, the two independently evolved light transduction pathways that coexist in both vertebrates and invertebrates now collaborate in collecting and processing information from photons. Although the evolutionary statement, 'survival of the

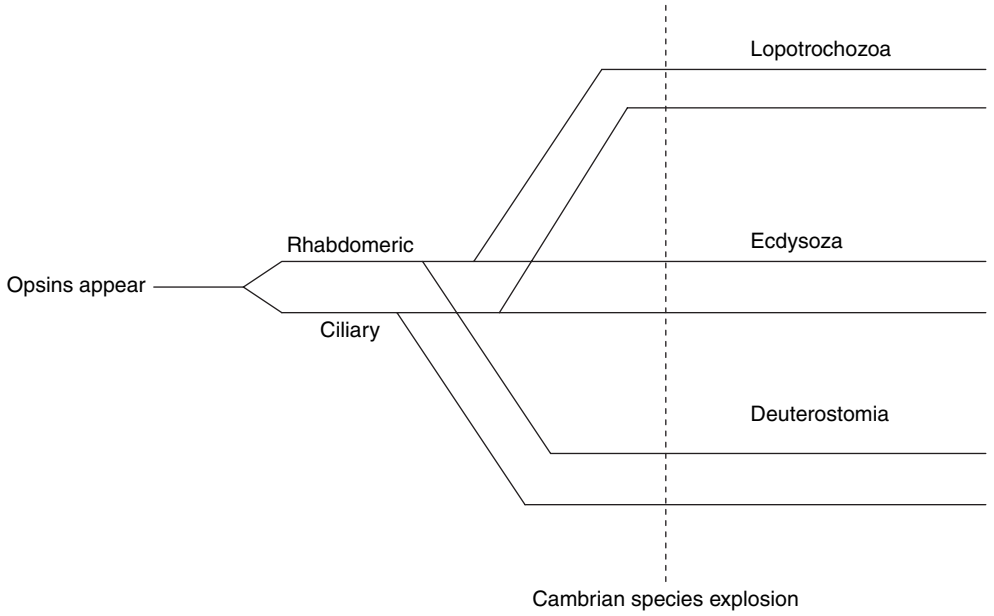

Figure 5 Schematic phylogeny of the Bilateria showing that the distinct rhabdomeric and ciliary organizaton of opsins preceded the split of the urbilateria. Adapted from Nilsson, D.-E. 2005. Photoreceptor evolution: ancient siblings serve different tasks. Curr. Biol. 15, R94–R96.

fittest' suggests a single survivor in an evolutionary race, here we see two contenders coexisting and even working together to inform adult organisms about information contained in light.

Third, since seven families of opsin have been described in vertebrates, including humans (see Figure 3 above), we can expect more surprises in how animals detect and use light. The additional opsins discovered recently have not yet been functionally characterized but the evidence suggests that there are no more opsins to be discovered (Kumbalasiri, T. and Provencio, I., 2005). Even so, figuring out how existing opsins might work together is an important challenge.

1.02.3.4 Other Solutions to Capturing Photons

As described, a persistent issues in the evolution of eyes is whether eyes evolved once or many times. Though it seems quite clear now that there were at least two kinds of phototransduction (e.g., ciliary and rhabdomeric) before the urbilateria split into three families (see Figure 4), energy and information are harvested in archaea and eukaryotic microbes using a system that clearly arose independently, via convergent evolution. Microbial, or type 1 rhodopsins, named to distinguish them from the visual pigments or type 2 rhodopsins, function to harvest light for energy, to guide phototaxis and probably many yet undiscovered functions (Spudich, J. L. *et al.*, 2000). While the number of known type 2 ('visual') rhodopsins has increased as described over the past several years (see above), the number of known type 1 rhodopsins has rapidly increased with the harvesting and genetic sequencing of ocean samples from a handful to over 800 (Spudich, J. L. and Jung, K. H., 2005). These type 1 rhodopsins are widely dispersed on the planet, found in organisms living in both fresh and sea water, salt flats, and glacial seas among others.

There are several fundamental differences between types 1 and 2 rhodopsins. First, there is no evident phylogenetic relationship between the genetic sequences of type 1 and type 2 rhodopsins. As more type 1 opsins are discovered, a connection may become apparent, but given the current state of knowledge, this seems unlikely. Second, the type 1 rhodopsins reveal convergent solutions to the mechanisms for converting photon energy. Both rhodopsin types consist of seven transmembrane domain proteins and, in each, retinal is attached in a Schiff base linkage via a lysine residue in the seventh helix (Spudich, J. L. *et al.*, 2000). However, type 1 rhodopsin (25–30 kDa) has a different organization of its intramembrane domains from type 2 rhodopsin (35 kDa), which reflects the fundamental difference in their signaling cascades.

Whereas type 1 rhodopsins function within the membrane to pump ions or signal to other integral membrane proteins, type 2 rhodopsins signal via G proteins, receptor kinases via the cytoplasmic loops (see above and Spudich, J. L. *et al.*, 2000). Retinal is used in association with both apoproteins but these are photoisomerized quite differently. In the familiar, type 2 rhodopsins, 11-*cis*-retinal is transformed to all trans upon absorbing light while in type 1 rhodopsins, all-*trans*-retinal is transformed to 13-*cis* when absorbing light.

Taken together, the remarkable convergence of type 1 and 2 rhodopsins suggests that in the course of evolution, an opsin apoprotein, associated with retinal has been discovered and exploited twice. Clearly, when the seven transmembrane protein is appropriately solvated with retinal, it is useful for transforming the energy of photons into more useful forms. This also suggests that progenitors of the type 1 opsins may have existed in earliest evolution before the divergence of archaea, eubacteria, and eukaryotes. This means that the light-driven ion transport mechanism for deriving energy used in association with retinal 1 preceded the evolution of photosynthesis as a means for using the sun's energy (Spudich, J. L. and Jung, K. H., 2005). We can now wonder whether a proto eye-like structure using rhodopsin 1 remains to be found that would allow a comparison of an additional independent solution to extracting information from light.

1.02.4 How Did Eyes Evolve?

Eyes exist in a variety of shapes, sizes, optical designs, and locations on the body, but they all provide similar information about wavelength and intensity of light to their owners. Different tissues have been recruited to build lenses and retinas across the phyla (Fernald, R. D., 2006). In contrast, all eyes share the same mechanism of absorbing photons since the opsin–chromophore combination has been conserved across phylogeny. Despite new findings yielded by powerful molecular techniques, all evidence still suggests that eyes have a polyphyletic origin, particularly since the discovery that two photodetection systems had evolved prior to the split of the urbilateria into three families. Clearly, eye as we know them contain homologous molecules responsible for many structural, functional and even developmental features. Given a growing list of homologous gene sequences among molecules in the eye across vast phylogenetic distances, the challenge is now to discover what makes the eyes of *Drosophila*, squid, and mouse so different. Understanding what makes eyes different may be a bigger challenge than finding what they have in common.

It seems increasingly evident that as eyes evolved, different functional mechanisms have been generated by recruiting existing gene programs. From genome sequencing, we know that there are far fewer genes in organisms than previously thought, so the use and reuse of genes and their products in combinatorial assemblies as reported for known genomes make sense. In the development of eyes, this seems to be the rule not the exception. Specifically, in the evolution of eyes, it seems likely that light sensitivity evolved early in the Cambrian in the form of a proto-opsin molecule in association with the chromophore, retinal. This molecular combination, sensitive to light, became associated with the genes *pax6* (Sheng, G. *et al.*, 1997), and possibly, *eya* (based on its phosphatase activity (Li, X. *et al.*, 2003)). One can imagine that this combination was recruited and worked well in early evolved eyespots and other light-sensing organs. It would not be surprising, for example, to find these genetic players in the recently described eye without a nervous system (Nordström, K. *et al.*, 2003).

Important insights about how regulatory gene networks might have evolved comes from what is called the 'hox paradox' (Wray, G. A., 2002). During development, orthologous genes are expressed in superficially similar domains during embryonic development of very different organisms (e.g., *Drosophila*; mouse) yet these embryos produce adults that are anatomically quite distinct having very few structures with common ancestors. Though not completely resolved, one resolution of this paradox is that there has been evolutionary convergence in the use of some genes and hence apparent homology (Wray, G. A., 2003). It seems that this is the likely scenario for the evolution of eyes. Some genes have been recruited into regulatory gene networks repeatedly, possibly committed early in evolutionary history and kept because they simply work well.

As different eye types evolved over time, there was probably repeated recruitment of particular gene groups, not unlike improvisational groups of actors, interacting to produce candidates for selection. The evolutionary fiddling through which various combinations or routines were tried could have led to numerous parallel evolutionary paths for eyes as we now envisage.

From this, two different mechanisms for transmitting the photic information to surrounding cells were

selected for, one in ciliary and one in rhadomeric photoreceptors. These two systems are likely present in all organisms as described above for worms and mice. The big surprise is that both of these transduction systems persisted with each selected as the primary visual system for a major branch of animals. So, the answer to the question of whether eyes evolved from a single prototypical eye (monophyletic), or whether they evolved repeatedly (polyphyletic), appears to be that quite evidently eyes arose at least twice and probably many times. And, as described above, given the vast number of organisms using rhodopsin 1, we should not be surprised if additional eyes appear in the biological world in the future.

1.03.1 Introduction

Rochon-Duvigneaud A. (1943, p. 453) captured the essence of a bird as "a wing guided by an eye." Both in popular imagination and in science, the phrase unites the defining characteristics of birds, flight with vision as the primary sense. Wings are the essential attribute of all birds or, for flightless birds, their ancestors.

Wings and vision diversified together, to give the range of ecology and behavior of living birds (Gill, F. B., 2007). Bats have remarkable powers of echolocation (Nachtigall, P. E. and Moore, P. W. B., 1988), but compared with birds their ecology and behavior is restricted. Vision provides spatial information at the speed, resolution, and range necessary to guide flight and the other behaviors that make birds so interesting (Perrins, C. M., 1990; Davies, M. N. O. and Green, P. R., 1994; Gill, F. B., 2007).

But how does an eye guide a wing so successfully? All eyes, irrespective of optical structure and evolutionary origins, perform the same essential tasks. They capture light and determine three primary attributes: the direction of the source, its intensity, and its spectrum. Although visual perception requires complex central neural processes, the eye exerts fundamental constraints on the information made available to the brain. Basic performance criteria of eyes that are essential for understanding visual physiology, and how vision is matched to behavioral needs, include (1) the absolute threshold in dim light, (2) the intensity or chromatic contrast thresholds for discriminating between two sources, (3) the spatial resolution, (4) the rate at which information is acquired, and (5) the cyclopean and binocular visual fields. These limits to vision set by the eye are essential for understanding visual physiology, and how vision is matched to behavior and ecology.

Rochon-Duvigneaud alluded to visual abilities in the second part of his description of a bird, ". . . ce qui exige la précision et la vitesse des fonctions rétiniennes" [the requirement for precision and speed in retinal processing]. Here he recognized the two main functional divisions of an eye: (1) an optical imaging system and (2) a photoreceptor array (retina) that starts image analysis. Rochon-Duvigneaud chose to emphasize the primary importance of the retina in determining visual capability (see Sections 1.03.6 and 1.03.7, and these have been reviewed by Meyer D. B. (1977) and Granda A. M. and Maxwell J. H. (1979)). However, as we show here, the relationship between behavioral ecology and visual mechanisms is reflected in both optics and retinal structure.

Sections 1.03.2, 1.03.3, 1.03.4 and 1.03.5 describe the optics of bird eyes and how the ways in which they vary affect the key properties of the image. Subsequent discussions suggest how these variations may be interpreted as adaptations to particular behaviors and ecological conditions. Among these image properties is the visual field, that is, the volume of space imaged on the retina, which limits visual information that is available at any one instant. The two monocular visual fields are combined to provide the total visual field (the cyclopean field), but they also overlap to provide a region of binocular vision. Section 1.03.5 concludes by summarizing the behavioral and ecological factors that are associated with different types of visual field.

1.03.2 Fundamental Constraints on Bird Eyes

1.03.2.1 Size and Information Capacity

In retrieving optical information from the environment, all eyes are constrained by the same fundamental problems that limit sensitivity and spatial resolution. In essence, there is always a trade-off between these two fundamental visual capacities; if there are few quanta in the image, then resolution cannot be high, and if the eye is designed to achieve high spatial resolution, it cannot do so at low light levels (Land, M. F. and Nilsson, D.-E., 2002). However, while this fundamental problem cannot be overcome, it can be mitigated by optical design, by topographical variation in the way that the retina samples the image, and by flexibility in the way that photoreceptors are pooled to sample the image at different light levels (Snyder, A. W. *et al.*, 1977). Optically, a bigger eye is better; a large pupil admits more light and has a higher diffraction limit to spatial resolution (Land, M. F. and Nilsson, D.-E., 2002; chapter 3). This raises fundamental questions about the selective forces that influence eye size and how information gain can be optimized for a particular set of environmental conditions within an eye of a particular size. Phototransduction and photoreceptors are metabolically costly (Laughlin, S. B., 2001a; 2001b), and it is clear that eyes should optimize the use of each photoreceptor cell. Shannon information encoded by each receptor is a good measure for predicting the trade-off between photon catch and receptor size (and hence spatial resolution) for natural images (Snyder, A. W. *et al.*, 1977; 1986; Hateren, J. H. van, 1992). Maximization of information capacity may account for features such as topographical variation in the receptor array, flexible neural pooling with light adaptation (Snyder, A. W. *et al.*, 1977; Srinivasan, M. V. *et al.*, 1982; Hateren, J. H. van, 1992), and the operation of pupils (Laughlin, S. B., 1992).

A clear example of how the retina can have specialized regions that sample the image in different ways is seen in the foveae and linear retinal areas in many bird species (reviewed by Meyer, D. B., 1977). Particularly striking examples of such regional specialization are the deep foveae of raptors, which act as telephoto lenses. These foveae are thought to achieve high resolution and low sensitivity in the fovea, while higher sensitivity and lower resolution are achieved outside the fovea (Snyder, A. W. and Miller, W. H., 1978). Overall birds have many types of retinal regional specializations, which have been interpreted with respect to both ecology and behavior (reviewed by Meyer, D. B., 1977). These include multiple foveae and linear areas in which a high density of photoreceptors and ganglion cells are arranged in an approximately horizontal band across the field of view serving lateral vision. But there may also be an area of the retina in which large and low-density ganglion cells serve forward vision. Both arrangements have been described in the retinae of shearwaters (Procellariidae) (Hayes, B. *et al.*, 1991; Hart, N. S., 2004). Photoreceptors and the Retina discusses regional specialization of receptors and color vision.

1.03.2.1.1 Costs of increasing eye size

Given that vision is important to birds, a simple prediction based on the above sections is that their eyes should be absolutely large. However, increased eye size is not without costs: as eye size increases, there will be a corresponding increase in receptor numbers, which has a metabolic cost (Laughlin, S. B., 2001a; 2001b), and eye mass will also increase. One of the fundamental constraints upon the evolution of birds has been selection for both reduced body mass and the distribution of mass toward the body core. This is a manifestation of the high power to low body mass ratio, which is considered to be one of the most important constraints that has shaped the evolution of birds (King, A. S. and King, D. Z., 1980). Single-chambered eyes are essentially heavy fluid-filled chambers. In flying birds, their increased size is probably countered by selection against (1) having a disproportionately heavy head, which is likely to destabilize flight, and (2) an absolute increase in body mass (King, A. S. and King, D. Z., 1980).

1.03.2.1.2 Eye-size allometry and ecology

The metabolic and weight costs of increasing eye size need to be compensated by advantages. Given that both absolute sensitivity (quantum catch) and spatial resolution can theoretically benefit from increasing size, it is of interest which criterion is in practice most significant. This clearly requires careful comparative analysis of the behavior and ecology of individual species or taxa at the level of the family or order, but some general trends have been discerned by comparing gross differences across a range of taxa.

Consideration of selection for eye size needs to take account of the overall relationship between eye size and body size. For 104 species of flying birds (each from a different family, with body masses between 6 g and 4.9 kg), eye mass scales as $(\text{body mass})^{0.68}$ (Brooke, M. D. L. *et al.*, 1999). This scaling is close to that for brain size, so that the ratio of eye mass to brain mass is fixed. An interesting observation was that there is no clear relationship between flight speed and eye size (Brooke, M. D. L. *et al.*, 1999), as might be expected if visual ability (e.g., integration time or spatial resolution) were related to speed of movement.

If body size is taken into account, avian eye size among certain taxa appears to be best predicted by the time at which the birds are active and to a lesser extent by the foraging strategy (Garamszegi, L. A. *et al.*, 2002). This general conclusion is supported by findings that passerines with comparatively large eyes start singing earlier in the day (Thomas, R. J. *et al.*, 2002) and shorebirds with large eyes tend to forage at night (Thomas, R. J. *et al.*, 2006). However, both diurnal raptors (Accipitridae) and nocturnal owls (Strigidae) have larger eyes than other families (Brooke, M. D. L. *et al.*, 1999; Garamszegi, L. A., *et al.*, 2002), indicating that more-detailed analyses within these and other taxa are necessary to determine how eye size is related to behavior and ecology at a more specific level.

1.03.2.2 The Ambient Light Environment and Light Adaptation

No bird is active at a fixed illumination intensity. When an eagle forages with full sunlight illumination, light levels could be 10^9-fold higher than those experienced by an owl in the same area under starlight (Martin, G. R., 1990). The eagle may experience a 1000-fold range of light levels between sunrise and noon, while the owl may experience a 10^6-fold range between sunset and a moonless night. To operate across these light ranges, eyes use both optical and retinal mechanisms to adjust sensitivity and resolution.

It is clear, however, that optical mechanisms to cope with light level changes are restricted. The pupil, controlled by the iris, is the only mechanism able to adjust retinal illuminance. This has a restricted dynamic range, and its effect may be

attenuated by the oil droplets (see Section 1.03.6.2). Although it can probably equilibrate rapid changes in retinal illumination between sun and shade, the pupil cannot compensate for the full-range light levels. For example, in rock pigeon (*Columba livia*; henceforth pigeon), the pupil can change retinal illumination by about 16-fold, which is similar to the range of the iris effect in humans (Marshall, J. *et al.*, 1973). Species that constrict the pupil to a pinhole or slit achieve a wider range of control. Such pupils are common among mammals, but among birds they occur only in skimmers (Rynchopidae) (Walls, G. L., 1942; Zusi, R. L. and Bridge, D., 1981). A small pupil increases diffraction and so is optically undesirable in a good eye (Laughlin, S. B., 1992). This view seems to be supported by the king penguin (*Aptenodytes patagonicus*), whose pupil does have a large dynamic range but is probably mainly adapted for seeing well in dim light at depth (see Section 1.03.3.1.3). The king penguin's fully constricted pupil forms a pinhole (diameter ≈0.65 mm) and when dilated ≈12.7 mm, which achieves a 300-fold range of retinal illumination (Martin, G. R., 1999). The penguin's pupil may allow the retina to remain dark adapted when the bird is at the surface. This will ensure that when at depth on a foraging dive and the pupil is fully dilated, the eye will be appropriately adapted to the ambient illumination. King penguins regularly dive to 200–300 m where light levels, even at midday, are equivalent to lower night-time levels (Martin, G. R., 1999).

1.03.3 Describing and Comparing Optical Structure of Avian Eyes

Vertebrate eyes have two principal refractive components, lens and cornea, separated by a variable aperture (Figure 1). This simple design embodies a number of degrees of freedom, which are capable of producing a range of optical performance. Variations in optical design can involve (1) the shape and relative positions of the principal refractive surfaces, (2) the effective refractive index of the lens, (3) the relative and absolute sizes of optical components, and (4) the size of the pupil aperture. The outcome is that when viewing the same scene, retinal images in different eyes can have quite different characteristics. In particular, images may differ in absolute size and brightness, and the angular extent of the proportion of space imaged upon the retina. That is the monocular retinal visual field.

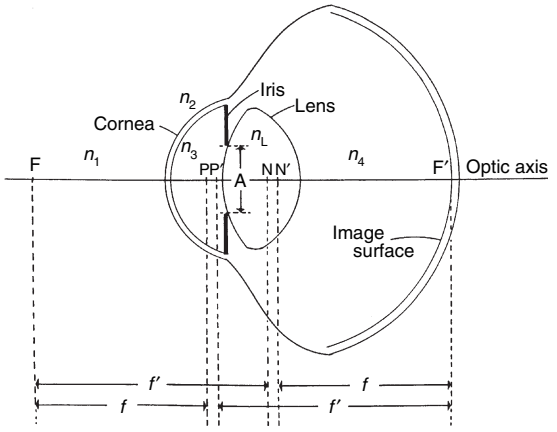

Figure 1 The general optical design of birds' eyes showing the main optical parameters defined in a schematic eye model. N, N′ are the nodal points; P, P′ are the principal points; F, F′ are the focal points of the optical system. They describe the points in a perfect optical system, through which a bundle of light rays would appear to pass and focus. They are shown positioned along the optic axis, which is assumed to be the axis of symmetry for the optical system. The distance *f* and *f′* between the nodal points and the focal points are the anterior and posterior focal lengths. The reason why there are two focal lengths for an eye is that the object and image points occur in media of different refractive index: n_1 (air) and n_4 (vitreous humor); n_2 and n_3 are the refractive indices of the cornea and aqueous humor; and n_L is the calculated equivalent bulk refractive index of the lens. An amphibious eye in water will have a single focal length and the cornea will not have any power since the refractive index of water and of the aqueous humor are equal. *A* is the diameter of the pupil defined by the margins of the iris. A schematic eye model such as this will only apply to paraxial rays that are close to the optic axis; it will not accurately describe optical parameters for peripheral rays. From these schematic eye parameters the refractive power of the cornea F_C, the lens F_L, and the whole eye F_E are calculated, and these are the important tools for making comparisons of the kind shown in Tables 1 and 2 and discussed in the text.

A useful basis for describing the general optical structure of an eye is the schematic eye model (Hughes, A., 1977; Martin, G. R., 1983; Hughes, A., 1986; Land, M. F. and Nilsson, D.-E., 2002). A diagram usually accompanies this mathematical description of the optics (Figure 1). The model normally represents a hypothetical average for a given species. Figure 2 illustrates schematic eyes of five species, namely, tawny owl (*Strix aluco*), common starling (*Sturnus vulgaris*), ostrich (*Struthio camelus*), Manx shearwater (*Puffinus puffinus*), and pigeon. Schematic eye models are also available for barn owl (*Tyto alba*) and chicken (*Gallus domesticus*;

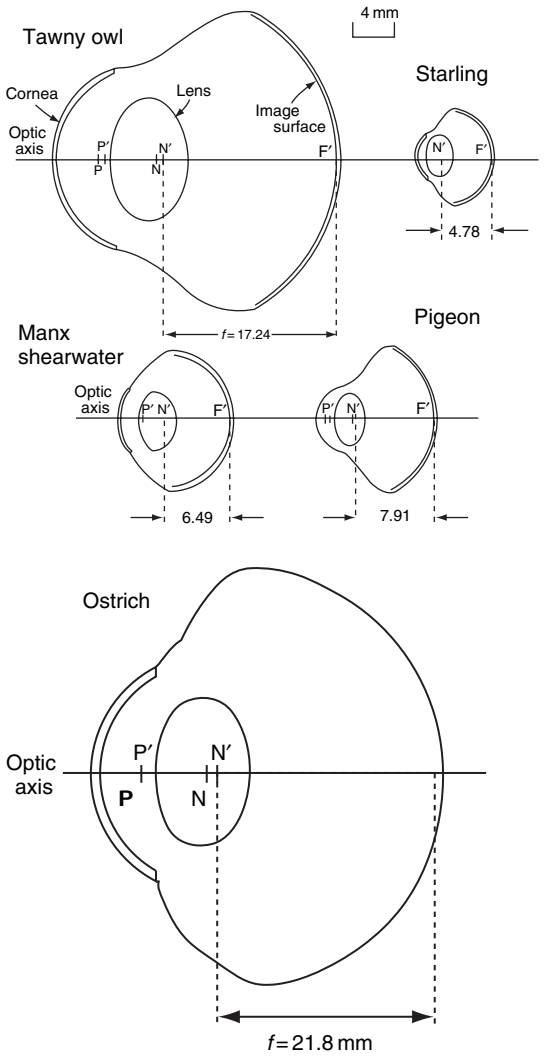

Figure 2 Scaled diagrams of the schematic eye models of five bird species. Also shown is the overall shape of the eye in an approximately horizontal plane. Symbols as in Figure 1. All numerical values are in millimeters. Tawny owl (*Strix aluco*; Martin, G. R., 1982), common starling (*Sturnus vulgaris*; Martin, G. R., 1986a), rock pigeon (*Columba livia*; Marshall, J. *et al.*, 1973; Martin, G. R. and Brooke, M. D. L., 1991), manx shearwater (*Puffinus puffinus*; Martin, G. R. and Brooke, M. D. L., 1991), and ostrich (*Struthio camelus*; Martin, G. R. *et al.*, 2001).

Schaeffel, F. and Howland, H. C., 1988; Schaeffel, F. and Wagner, H., 1996). Description of an eye by a small number of key variables allows interspecific comparisons of optical structure and performance. These in turn allow correlations with key environmental variables, and hence an exploration of how vision may be related to behavioral and ecological variables.

1.03.3.1 Optical Design

1.03.3.1.1 Eye size

Ostriches have eyes that are amongst the largest of any land vertebrate, with an axial length ≈39 mm, but overall there is wide variation of eye size among birds (Brooke, M. D. L. *et al.*, 1999). Figure 2 presents scaled schematic eye diagrams of eyes whose size differs over a fivefold range. The most important optical parameter associated with eye size is the anterior focal length (or posterior nodal distance, PND) as this determines the retinal area over which the image is spread. Miller W. H. (1979) showed that a large PND is essential for an eye to achieve the maximum theoretical limit of visual resolution. This is because there is a lower limit (about 1.5 μm) to diameter of a photoreceptor, which (in the absence of a diffraction limit) sets a maximum packing density of the retinal sampling (see Section 1.03.2.1).

Thus, it is a simple prediction that high-resolution eyes should be absolutely large, as does indeed seem to be the case. The highest psychophysical resolution known in any animal is for the Australian wedge-tailed eagle (*Aquila audax*), whose eye has an axial length of about 33 mm (PND 22 mm; Reymond, L., 1985). By comparison, the larger eyes of ostriches have an estimated maximum resolution (based on retinal ganglion cell density and image size) about seven times lower than that of the eagle. This suggests that large eye size in ostriches is associated with high sensitivity (nocturnal or crepuscular) vision, rather than high-resolution diurnal vision as in the eagle (Boire, D. *et al.*, 2001).

The ostrich eye supports the argument that a relatively large eye size is often associated with nocturnality (see Section 1.03.2.1.2), allowing high absolute sensitivity rather than high spatial resolution. Among birds tawny owls provide the best test of this. Their eyes are ≈29 mm long and their absolute visual threshold has been behaviorally determined (Martin, G. R., 1977; 1986b). The tawny owl has an absolute visual threshold which is similar to that of a nocturnal mammal, the domestic cat (*Felis domesticus*), and is about 2.5 times lower than that of humans and about 100 times lower than that of pigeons. Owl eyes are not, however, the most sensitive in the animal kingdom; that accolade goes to some deep-sea invertebrates whose relative sensitivity is nearly 100 times greater (Land, M. F. and Nilsson, D.-E., 2002). The advantage that a large eye brings the owl is that although its retina is dominated by rod photoreceptors, at high (daytime) light levels its resolving power

is similar to that of the smaller, and cone-dominated, eye of pigeons. The resolution of an owl eye markedly exceeds the resolution of a pigeon as light levels fall (Martin, G. R., 1986b). Thus, the tawny owl appears to have a good eye as defined by Land M. F. and Nilsson D.-E. (2002) in that it combines both relatively high resolution and high sensitivity. So far, few bird eyes have been studied by the behavioral measures, plus analysis of optics, that are necessary to compare the trade-off between resolution and sensitivity in other species.

1.03.3.1.2 Contributions of lens and cornea

Table 1 compares key parameters of the eyes of the five species illustrated in Figure 2. That these eyes differ in their total refractive power is a manifestation of eye size, since a smaller eye must have a higher refractive power to bring the image of a distant object to focus on the retina. Of more interest is the ratio of the power of the lens to that of the cornea ($F_L : F_C$). This parameter reflects how the two optical components (lens and cornea) contribute to the total power, and it does vary substantially between species.

Starling, owl, and ostrich eyes have an $F_L : F_C$ ratio that is close to unity, that is, the lens and cornea contribute approximately equal refractive power. These eyes share a similar optical design, despite the nearly fivefold difference in length, differences in their shapes, and of course behavioral differences between the three species. In short, these eyes are approximate scaled versions of a single optical design. An $F_L : F_C$ ratio of unity is not, however, universal. In pigeon the cornea contributes about 2.5 times the refractive power of the lens, while in the Manx shearwater the situation is almost reversed, with the lens contributing considerably more than the cornea. These differences in optical structure are functionally significant in that the total refractive power of the pigeon and shearwater eyes differ markedly. Although their eyes are of equal size, the effective focal length of shearwaters is less than that of pigeons, and therefore, the retinal image is smaller. Pigeons, by virtue of a larger image, have the potential for higher spatial resolution, whereas shearwaters have a smaller and hence brighter image, with the potential for greater sensitivity. A similar effect is achieved within a single eye by telephoto optics in the deep foveae of raptors, which increase the effective focal length of the eye and hence image size at the expense of brightness (Snyder, A. W. and Miller, W. H., 1978).

1.03.3.1.3 Amphibious habits and optical design

Species that need to see both in air and underwater are faced with a specific optical problem. Immersion abolishes the refractive power of the cornea, because it now separates media (water and aqueous humor) of near-identical refractive index. If an amphibious eye is to focus both in air and in water, the lens must be able to compensate for the loss of corneal refraction. Should an aerial eye, like that of a starling, be immersed in water, its lens would need 124 diopters of additional refractive power.

This consideration led Sivak J. G. (1976) to propose that eyes designed for well-focused vision in air and water should have a relatively flat cornea, and hence low power. The lens may then more easily compensate for the effects of immersion. Such an optical design is indeed found in penguins (Sivak, J. G., 1976; Martin, G. R. and Young, S. R., 1984; Martin, G. R., 1999), and in the albatrosses (*Diomedea* spp.). However, the scaling of eyes, as discussed above (see Section 1.03.3.1.1), also predicts that the absolute power of the cornea should decrease as eye size increases.

Table 2 shows that ostriches, king penguins, and two albatross species have similar-sized eyes.

Table 1 Comparison of eye size (axial length) and certain schematic eye parameters in five species of birds

	F_{EYE} (D)	F_L (D)	F_C (D)	$F_L : F_C$	Axial length (mm)	Focal length (mm)
Starling	209	112.5	124.6	0.90	7.92	4.78
Shearwater	154	108.6	68.1	1.60	11.82	6.49
Pigeon	126	38.7	95.9	0.40	11.62	7.91
Tawny owl	58	29.9	35.7	0.84	28.50	17.24
Ostrich	45.9	27.5	25.4	1.08	39.01	21.8

Schematic eyes for these species are show diagrammatically in Figure 2, where sources are also given. Focal length is the anterior focal length (posterior nodal distance, PND); Refractive powers are in diopters (D).

Table 2 Eye axial length, corneal refractive power (F_C in diopters, D), and radius of corneal curvature (R, mm) in 11 species of bird

	Axial length (mm)	F_C *(D)*	*R (mm)*
Ostrich	38	25.4	13.23
King penguin	25	10.2	32.9
Grey-headed albatross	37	22.8	14.7
Black-browed albatross	39	23.3	14.4
Tawny owl	28.5	35.7	9.4
Humboldt penguin	18.7	29.8	11.3
Rock hopper penguin		17.7	19.1
Gentoo penguin		15.1	22.4
Manx shearwater	11.82	68.1	4.9
Rock pigeon	11.62	95.9	3.5
Common starling	7.92	124.6	2.70

Sources are given in Figure 2 and Table 3 with the exception of rockhopper and gentoo penguins (Sivak, J. G., 1976).

Albatrosses make shallow dives but appear to detect food from the surface, whereas king penguins often forage at great depth. Ostriches and albatrosses, whose vision is likely to be adapted primarily to aerial conditions, share a similar eye design and have corneas of relatively low refractive power compared with smaller-eyed birds (Table 1). In these large birds the relatively low corneal power can be attributed to scaling of the basic aerial avian eye. However, king penguins have a cornea of even lower refractive power that can be interpreted as an adaptation to the demands of vision in both air and water. Unfortunately, no psychophysical data are available for any penguin to determine whether similar resolution is achieved in both air and water.

It is also noteworthy that when any eye enters water the brightness of the retinal image decreases. This is because the magnifying effect of the cornea on the pupil is lost, and so the effective entrance pupil decreases. In addition, diving to any depth results in a marked decrease in illumination. King penguins dive to light levels equivalent to night at the surface and are in effect nocturnal foragers (Martin, G. R., 1999). Thus, the large size of king penguin eyes may be primarily an adaptation to low light levels, while the relatively low-power cornea could be described as an adaptation to reduce the accommodative demand upon the lens when moving between air and water. There is, however, another possibility. The pinhole pupil of a king penguin eye in air (see Section 1.03.2.2) will give a large depth of focus, and it may be that its eye is in fact primarily for aquatic conditions (emmetropic in water), with the optics effectively bypassed at the surface.

1.03.3.2 Accommodation

The larger the eye, the higher the requirement for an accommodative mechanism, since smaller eyes have a greater depth of field than larger ones (Land, M. F., 1981; Martin, G. R., 1994a). Accommodation in mammals relies on deformation of the lens, whereas birds can control accommodation using both the lens and the cornea (Glasser, A. and Howland, H. C., 1996; Ott, M., 2006). It is not clear under which circumstances a particular mechanism is used. For example, it may be that for certain distances only the cornea is used, and for others the lens and cornea work in tandem. The iris is an important component of this system. It causes the deformation of the lens by squeezing the annular pad (Figure 1), which in turn causes the anterior lens surface to bulge, and hence to increase in refractive power. It is also not clear how independent the two functional effects of the iris are: accommodation and control of image brightness. There are marked interspecific differences in the density of the muscle fibers involved in the mechanisms of accommodation in birds, for example, they are described as bulky and strong in chicken but scarcely developed in pigeon (Glasser, A., 2003); the functional significance of these differences is not known. It is argued that in all birds accommodation serves to increase the power of the cornea and/or the lens (Glasser, A. *et al.*, 1994; 1995). However, in the relaxed eye all parts of the retina are not necessarily focused at infinity. In common starlings the frontal visual field appears to be emmetropic for near objects when the lateral field focuses at infinity (Martin, G. R., 1986a). Similarly, in the frontal parts of the pigeon, visual field resolution is best for a viewing distance of 100 mm and cannot focus more distant objects (Rounsley, K. J. and McFadden, S., 2005).

1.03.4 The Kiwi: Regressive Evolution of a Bird Eye

Writing in the *Origin of Species*, Darwin C. R. (1859, p. 186) described eyes as "Organs of extreme perfection and complication" and argued that they set a particularly difficult challenge to his theory of evolution. That challenge has been addressed (Land, M. F. and Fernald, R. D., 1992; Nilsson, D. E. and Pelger, R. F., 1994), but Darwin's concern about perfection permeates twentieth-century surveys of vertebrate eyes (e.g., Walls, G.

L., 1942; Rochon-Duvigneaud, A., 1943; Duke-Elder, S., 1958). It is therefore interesting that under certain conditions eyes regress in evolution, leading to blindness in species such as the cave fish (*Astyanax mexicanus*) (Jeffery, W. R., 2005; Leys, R. *et al.*, 2005).

Although blind cave dwellers are familiar, there are few well-documented instances of partial regression of eye structure and vision, and here kiwis (*Apteryx* spp.) are a good example (Martin, G. R. *et al.*, 2007). Nocturnality along with freedom from some of the constraints on eye size that are faced by flying birds (see Section 1.03.2.1.1) might predict that kiwis should have large eyes. Flightless Struthioniformes (ostriches and allies) and Sphenisciformes (penguins) have among the largest of any vertebrates (see Section 1.03.3.1.1).

The five living kiwi species have evolved in New Zealand over a period of 80 million years without terrestrial mammals (Tennyson, A. J. D. *et al.*, 2003; Wilson, K.-J., 2004). Kiwis are nocturnal, flightless, cursorial birds of the forest floor, where they forage for soil and surface-dwelling invertebrates (Marchant, S. and Higgins, P. J., 1990). Little is known about their senses, although they use smell to find food (Wenzel, B., 1968).

Kiwi eyes are able to accommodate, showing that the optical system is functional (Howland, H. C. *et al.*, 1992), but their axial length and equatorial diameter (both ≈7.0 mm) are exceptionally small with respect to body mass (see Section 1.03.2.1.1; Brooke, M. D. L. *et al.*, 1999). The eye shape is similar to that of diurnal birds such as starlings and pigeons, not like the tubular eyes of owls (Martin, G. R., 1986b; Hall, M. I. and Ross, C. F., 2007). These small eyes are probably limited to the detection of gross detail within a nocturnal scene (Land, M. F. and Nilsson, D.-E., 2002). Furthermore, the visual fields are very small, and visual centers in the brain are almost absent. There is no discernable visual wulst, which is the main visual center in the forebrain (Reiner, A. *et al.*, 2004), whereas the relatively large olfactory and tactile centers (Martin, G. R. *et al.*, 2007) reflect a high concentration of tactile receptors around the bill tip, where the nostrils are (uniquely in birds) situated (Cunningham, S. J., 2006; Martin, G. R. *et al.*, 2007).

Kiwi is then the exception that proves the rule that vision is important to birds. Other ratites, such as the moa, cassowary, rhea, and ostrich, have large eyes (Worthy, T. H. and Holdaway, R. N., 2002). It seems safe to conclude that reduced vision is a derived characteristic in kiwi and a good example of adaptive regressive evolution (Jeffery, W. R., 2005). There is, however, a comparison to be made with nocturnal mammals such as rodents that, like kiwi, rely mainly on touch and smell. Perhaps vision cannot meet the perceptual challenges of nocturnal life on the forest floor.

1.03.5 Visual Fields

Among vertebrates, the eyes occupy many different locations in the skull (Walls, G. L., 1942). Frontal eyes, as in humans, have approximately parallel optical axes; colloquially the eyes look in the same direction. The two eyes receive very similar views. No birds, including owls (see Section 1.03.5.2.3), have eyes with parallel optical axes. Instead each eye views a different part of visual space, with various degrees of overlap. Visual fields of birds are diverse: the total visual fields and the areas of binocular overlap differ markedly in their size and location. These differences may have important consequences for behavior.

This section reviews the topography of visual fields in birds and discusses their functions. It is based on data obtained by an ophthalmoscopic reflex technique (Martin, G. R. and Katzir, G., 1994a), which has been applied to a wide range of species (Table 3). The technique allows visual field topography to be determined in alert birds and so represents visual field topography as it is in nature.

1.03.5.1 Describing Visual Fields

A visual field is the three-dimensional (3D) space within which the eyes can receive visual information at any one instant. Visual fields are described by an angular coordinate system based on conventional latitude and longitude and centered on the head. The center of the coordinate system is the intersection of the bird's median sagittal plane with the midpoint of a line joining the optical center of each eye (the nodal points). The equator is aligned in the median sagittal plane. The field is visualized by its projection onto the surface of a sphere that is centered on the head. As in cartography, mapping 3D visual fields on a flat surface causes distortions (Leys, R. *et al.*, 2005). To understand spatial relationships between features in the visual field, the spherical projection can be viewed from different directions, much as a globe can be viewed from various directions (Figure 3). Sections through the visual fields in different planes that pass through the center of the projection (approximately the center of the head) allow straightforward quantitative comparisons of field dimensions: for example, (1) the angular width

Table 3 Bird species (13 orders; 19 families; 31 species) and their visual field types

Struthioniformes
- Struthionidae
  - Ostrich *Struthio camelus* (type 1) (Martin, G. R. and Katzir, G., 1995)
- Apterygidae
  - Brown kiwi *Apteryx mantelli* (Martin, G. R. *et al.*, 2007)
  - Great spotted kiwi *Apteryx haastii* (Martin, G. R. *et al.*, 2007)

Spheniscidae
- Spheniscidae
  - Humboldt penguin *Spheniscus humboldti* (type 1) (Martin, G. R. and Young, S. R., 1984)
  - King penguin *Aptenodytes patagonicus* (type 1) (Martin, G. R., 1999)

Procellariiformes
- Diomedeidae
  - Black-browed albatross *Diomedea melanophris* (type 1) (Martin, G. R., 1998)
  - Gray-headed albatross *Diomedea chrysostoma* (type 1) (Martin, G. R., 1998)
- Procellariidae
  - Manx shearwater *Puffinus puffinus* (type 1) (Martin, G. R. and Brooke, M. D. L., 1991)
  - White-chinned petrel *Procellaria aequinoctialis* (type 1) (Martin, G. R. and Prince, P. A., 2001)
  - Antarctic prion *Pchyptila desolata* (Martin, G. R. and Prince, P. A., 2001)

Ciconiiformes
- Ardeidae
  - Cattle egret *Bubulcus ibis* (Martin, G. R. and Katzir, G., 1994a)
  - Reef heron *Egretta gularis* (Martin, G. R. and Katzir, G., 1994a)
  - Squacco heron *Ardeola ralloides* (Martin, G. R. and Katzir, G., 1994a)
  - Black-crowned night heron *Nycticorax nycticorax* (Katzir, G. and Martin, G. R., 1998)

Phoenicopteriformes
- Phoenicopteridae
  - Lesser flamingo *Phoeniconaias minor* (Martin, G. R. *et al.*, 2005)

Anseriformes
- Anatidae

Bucerotidae
Southern ground hornbill *Bucorvus leadbeateri* (type 1) (Martin, G. R. and Coetzee, H. C., 2004)
Southern yellow-billed hornbill *Tockus leucomelas* (type 1) (Martin, G. R. and Coetzee, H. C., 2004)
Passeriformes
Sturnidae
European starling *Sturnus vulgaris* (type 1) (Martin, G. R., 1986a)

In all species visual fields have been determined using the same ophthalmoscopic reflex method. Taxonomy follows Sibley C. G. and Monroe B. L. (1990).

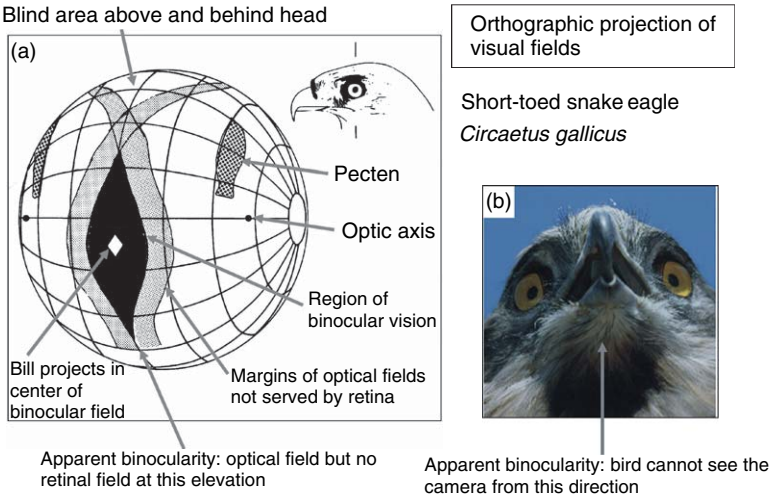

Figure 3 Depiction of visual fields. Example based on data for short-toed snake eagle (*Circaetus gallicus*). (a) Perspective view of an orthographic project of the visual field showing the binocular sector to the front of the head and the blind area above and the margins of the optical fields that are not served by retina. The projection of the optic axes, pectens, and of the bill are also shown. It should be imagined that the bird is placed at the center of a transparent sphere that surrounds the head and the projections of the various features are drawn onto the surface, the orientation of the head is depicted in the inset drawing, but the median sagittal plane of the bird lies is in the same plane as the equator of the projection that is vertical and contains the projection of the bill. (b) Photograph of a bird taken at a position in the sagittal plane below the bird that lies outside of the retinal visual field. This gives the impression that the bird has binocular vision at this point since it is possible to see into the eye. However, there is no retina serving vision at this elevation and so the bird could not see the camera.

of the binocular field in the plane of the bill or at the horizontal; (2) the angular width of the blind area above or behind the head; and (3) the total angular width of the visual field in a particular plane (the cyclopean field; see example in Figure 4).

1.03.5.1.1 Difficulties in estimating visual fields and binocular overlap

Casual examination of the eyes to estimate visual field parameters can be misleading, especially in exaggerating binocular overlap in the frontal field. Figures 3 and 4 exemplify this problem. The photograph in Figure 3(b) suggests that the bird is looking binocularly at the camera. However, the functional visual field (Figure 3(a)) determined by the ophthalmoscopic reflex (see Section 1.03.5) shows that although it is indeed possible to see into the eye (and hence the pupil is visible), the image falls outside the retina. In fact the eagle's optics produce a binocular field that is 40° wide in the horizontal plane, but functionally the field is only 20° (Figure 4). Similarly Figure 3 shows that there are elevations where it is possible to see into both eyes, but the eagle is blind because there is no retina. In summary, the frontal binocular field width is not maximized within the optics. A similar situation

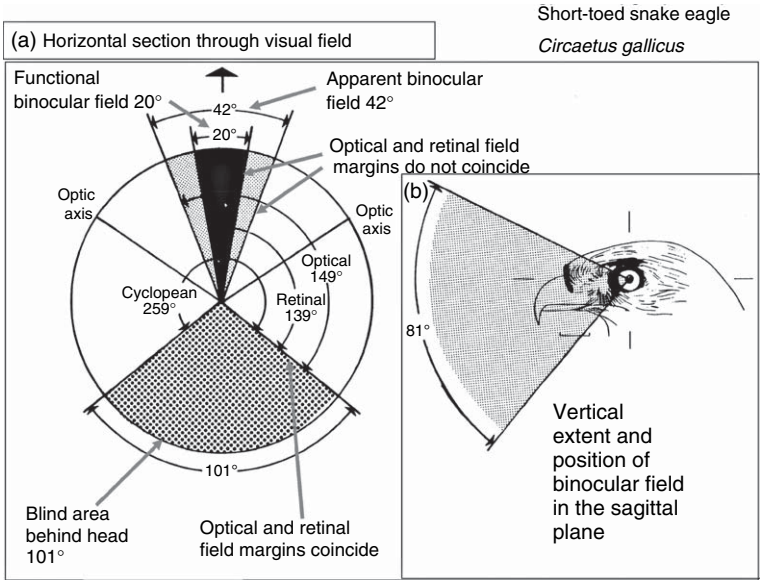

Figure 4 Depiction of visual fields. Example based on data for short-toed snake eagle (*Circaetus gallicus*). (a) Horizontal section through the visual field showing the key features in a single plane. The median sagittal plane of the bird is vertical and perpendicular to the plane of the drawing, and the bill points in the direction of the arrow at the top. Key features of the visual field are indicated. (b) The vertical extent of the visual field in the median sagittal plane (which is in the same plane as the drawing) relative to the bird's head as depicted in the drawing. In this plane the visual field is always binocular.

applies to other species, including ostriches, herons, and owls. The Function of Binocularity discusses the reasons to forego maximizing binocularity.

While there is a deficiency in frontal binocularity, to the rear of the head, in all birds examined, the margins of the optical and retinal fields coincide (e.g., Figure 4), to make maximum use of the optical image.

1.03.5.2 Types of Avian Visual Field

For the frontal field, and particularly the binocular field, there are three main types of visual field topography. It is hypothesized that the topography is determined primarily by feeding ecology or the requirements of provisioning young, rather than phylogeny or ecology (Martin, G. R. *et al.*, 2005). Of prime importance is the need for precise visual control of bill position, when attacking prey or feeding chicks, which is associated with a type 1 field (Figure 3). This applies whether the bird forages in air or water or is primarily diurnal or nocturnal. Birds species that exemplify different types of visual fields and their foraging ecology are depicted in Figures 5(b)–5(d).

1.03.5.2.1 Type 1 fields

Type 1 fields occur in diverse species (Table 3). The projection of the bill falls either centrally or just below the center of the frontal binocular region. This region is narrow and vertically extended, with a maximum width of 20–30°. Although the direction of the bill is approximately central within the binocular field, this does not necessarily mean that the bird can see its bill. Species that lunge or peck at food with the bill (e.g., pigeon, herons, albatrosses, and penguins) or take prey in the feet (eagles) probably cannot see their bill. Only for those that forage with open mandibles (e.g., starling) or manipulate and inspect items held in the bill (e.g., hornbills (Bucerotidae) and skimmers (Rynchopidae)) is the bill visible (Figure 5(b)).

The vertical extent of the binocular region in type 1 fields varies considerably. It is 80° in an eagle (Figure 3) but in herons extends 180° from directly above to directly below the head when the bill is horizontal (Figure 6). This arrangement allows a heron that is standing with the head horizontal to observe prey at its feet. The bird can remain motionless until prey is within striking distance. The extended binocular field gives rises to the often-illustrated ability of bitterns (*Botaurus*, *Ixobrychus* spp.) to look forward while the bill points skyward in a cryptic posture. Type 1 fields have a blind area to the rear of the head, which varies in width from about 40° in herons to 100° in eagles.

Apart from herons and raptors a number of species that need to locate their bill precisely have type 1

fields. Flamingos are filter feeders (see Section 1.03.5.2.2), but parents feed chicks by dripping liquid directly into the mouth, which requires precise bill position (Figure 5(b)). Similarly, Antarctic prions (*Pachyptila desolata*) filter feed on the wing and have to place their bill precisely at the water surface (Martin, G. R. and Prince, P. A., 2001). The prion has a type 1 field with the bill positioned in the lower half of the binocular region, and a 50° bind area behind the head. Skimmers (*Rynchops*) have an extraordinary method of foraging where the beak is held open in flight. The skimmer's lower mandible ploughs through the water and snaps shut when it touches an object (Zusi, R. L., 1996). The skimmer has a type 1 visual field and is one of the few species described that can see its bill tip. This arrangement could allow accurate bill placement and identification of what has been seized (Figure 5(b)).

1.03.5.2.2 Type 2 fields

Type 2 fields are characterized by a frontal binocular field $\leq 10°$ wide. The bill falls at the periphery or outside the visual field. Unlike many type 1 fields, full use is made of the available optical image, with no blind margin. The binocular field extends through approximately 180° in the sagittal plane, approximately from the horizontal in front of the head to the horizontal behind. This gives panoramic vision with complete coverage of the celestial hemisphere. There is no blind area above or to the rear.

Type 2 fields are typically found in species whose foraging is guided by nonvisual cues and also have precocial self-feeding chicks. Examples are filter-feeding ducks (e.g., mallard (*Anas platyrynchos*), shoveler (*Anas clypeata*), and pink-eared duck (*Malacorhynchus membranaceus*)) (Figure 5(d)) and long-billed probing shorebirds (Charadridae), which locate prey by touch with the bill tip (Gottschaldt, K. M., 1985; Piersma, T. *et al.*, 1998; Nebel, S. *et al.*, 2005).

1.03.5.2.3 Type 3 fields: owl eyes

Owls (Strigidae, Tytonidae) have a broad frontal binocular field $\approx 50°$ wide, with the bill tip just below the lower periphery (Figure 5(c)). An extensive blind area to the rear of the head reaches a maximum width of approximately 160° directly behind. The eye position appears to be frontal, as in humans, but in fact the eyes diverge by 55°. Moreover, as for type 1 fields, the binocular region is considerably narrower than it might appear, and not maximized within the optical image. Owls seize prey with their feet, which swing into the binocular area just before the strike. While the visual fields of owls are distinct from those of other species, it is not clear which aspects of their behavior and ecology underlie this specialization. It has been argued that extensive binocular overlap is associated with the nocturnality (Walls, G. L., 1942; Tansley, K., 1965). However, as we have mentioned, the binocular overlap is smaller than might be expected. Other nocturnal birds including oilbirds and nightjars (Caprimulgidae) and night herons (*Nycticorax* spp.) have type 1 visual fields (Figure 5(c)). Owl eyes are discussed further in Section 1.03.5.4.2.

1.03.5.3 Visual Fields and Eye Movements

In many species, eye movements are virtually absent (e.g., owls (Martin, G. R., 1984) and albatrosses (Martin, G. R. and Prince, P. A., 2001)), and where they do occur, they are nonconjugate (Wallman, J. and Pettigrew, J. D., 1985), which allows a wide range of visual field configurations (see examples in hornbills; Martin, G. R. and Coetzee, H. C., 2004). A notable change in visual field topography is the abolition of frontal binocularity and a corresponding reduction in the width of the blind area to the rear. This is exemplified in herons where the maximum eye movement amplitude is about 18° in the horizontal plane (Figure 7). The functional significance of visual field changes produced by eye movements is not clear. Increased visual coverage to the rear of the head may be significant. Although head movements are often important, as for humans, eye movements probably allow high-acuity regions to track or inspect a target.

1.03.5.4 The Function of Binocularity

The extent and position of binocular overlap and its relationship to visual foraging have received particular attention. The frontal binocular field of 20–30° is common to all type 1 fields (Section 1.03.5.3) and seems to be a general solution to a common problem. Nonetheless, the arrangement is not universal, which suggests that it is not concerned primarily with the flight control. Narrower binocular fields, linked to panoramic vision of the celestial hemisphere, are found in species that are both fast flying and maneuver within both open and woodland habitats (European woodcock, *Scolopax rusticola*, and mallard).

General accounts are influenced by the assumption that binocular vision (two eyes viewing the same location) results in stereopsis (Hughes, A., 1977).

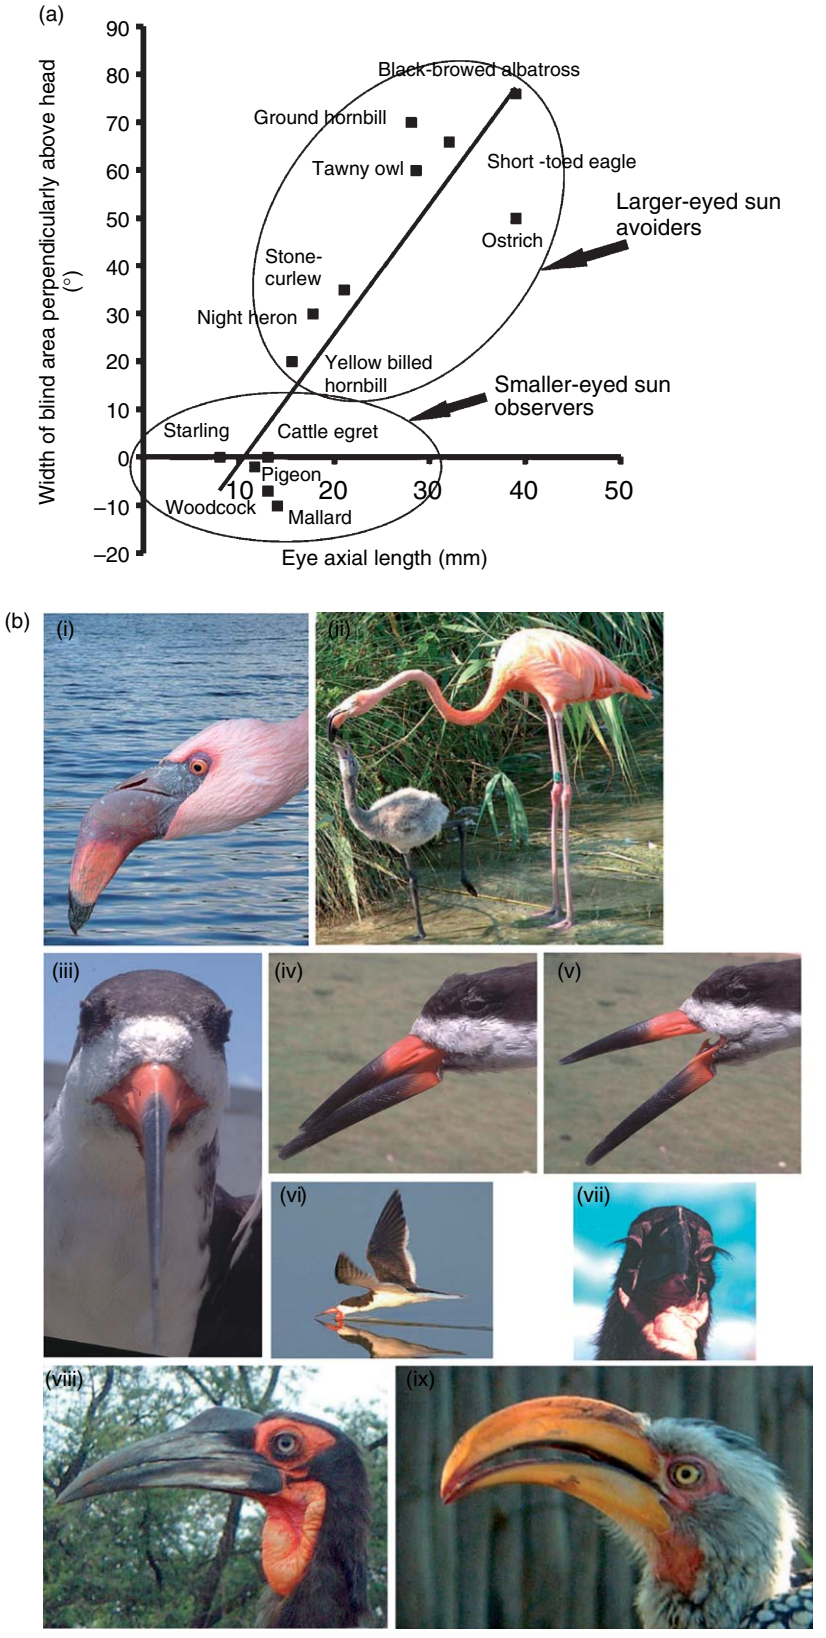

Figure 5 (*Continued*)

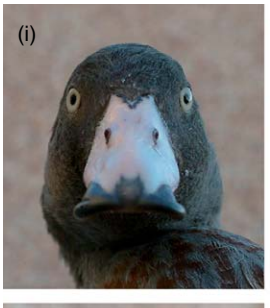
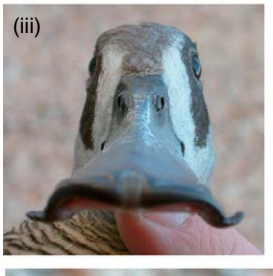
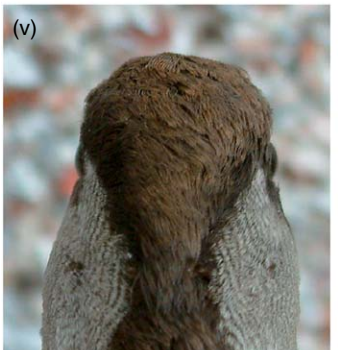
(c)

(d)







However, for birds the assumption that binocularity inevitably results in stereopsis is questionable (McFadden, S. A., 1993; 1994; Davies, M. N. O. and Green, P. R., 1994). The pigeon has depth perception and is sensitive to disparities of about 1 arc minute (compared to 4 s in humans), but it is doubtful that this ability is used in foraging (McFadden, S. A., 1993). Motion-parallax is probably an important source of depth information for birds (Kral, K., 2003) and cannot easily be ruled out. Although owls do have stereopsis (Nieder, A. and Wagner, H., 2000; Willigen, R. F. *et al.*, 2003), it is unlikely to provide a general

Figure 5 (a) Eye size and sunshades. The width of the blind area perpendicularly above the head as a function of eye axial length in 13 species of terrestrial birds. Positive values indicate the width of a blind area and negative values the width of a binocular field. All measurements employed the same ophthalmoscopic reflex technique and show values when the head is eld in its typical posture for the species. The line is the linear regression. The Spearman correlation between the two variables is significant ($r = 0.85$, $P < 0.005$, $n = 13$). Species are grouped as larger-eyed sun avoiders that have a blind area above the head and posses optic adnexa (eye lashes, eye brows) capable of shading the eye, and smaller-eyed sun observers that have vision above the head and do not have optic adnexa. (b) Examples of bird species whose visual fields are described in the text and in Table 3. Filter feeding. Flamingos (i) feed with their head upside down and filter microscopic particles from the water surface. This technique would not seem to require accurate bill placement guided by visual cues. However, flamingo visual fields show the characteristics of birds that feed by accurate visually guided pecking in which the bill is placed centrally within the binocular field. It is argued that this visual field configuration is necessary when feeding the chick. This entails accurately dripping crop-milk into the juvenile's open bill (ii) and this presumably can only be achieved by guidance from visual cues. Tactile feeding. Skimmers (iii–v) are unique in their feeding technique. They forage apparently blindly with the lengthened lower mandible trailing in the water as the bird flies a level straight course (iv). Birds may feed by both night and day. The bill is snapped shut on a prey item when triggered by tactile or vestibular cues produced when the mandible strikes prey. Skimmers' visual fields also show the characteristics of birds that feed by accurately visual guided pecking, but it is argued that this configuration is necessary not for accurate bill placement but for visual inspection of prey items caught during blind trawling. Precision-pecking and visually guided manipulation of items. Hornbills (viii, ix) have massive down-curved bills that are used to locate and excavate for, and manipulate, a wide range of prey and other food items. The birds have type 1 visual fields with binocular vision about the bill and eye movements of relatively large amplitude that can bring about marked changes in visual field configuration. All hornbills have relatively large eyes and have some of the most elaborate sun shade optical adnexa found in birds, including extensive brows and eye lashes (vii). (c) Examples of bird species whose visual fields are described in the text and in Table 3. Nocturnally active birds. Although apparently facing similar visual challenges in the nocturnal and crepuscular environment, these birds exhibit a wide range of visual field configurations that are probably related to particular foraging techniques. Oilbirds (i, ii) are arguably the most nocturnal of all birds and rarely, if ever, see daylight since they roost in caves during the day and only emerge to forage at night to feed on fruit in the tropical rain forest canopy. Although their eyes are relatively large and protrude noticeably from the skull, their visual fields show the characteristics of type 1 fields (Table 3), suggesting that accurate bill placement toward items may be guided by visual cues. However, these birds are also thought to employ olfactory cues in determining the general location of ripe fruits. A similar visual field configuration is found in nightjars (iii, iv), which take insect prey on the wing from the open airspace in twilight and at night. Despite being totally nocturnal kiwi (v) have relatively very small eyes and the smallest binocular and total visual fields yet recorded in a bird. It is possible that vision in these flightless birds has been subject to regressive evolution and that locomotion and food finding are guided primarily by olfactory and tactile cues gained from the bill tip. In contrast owls (vi) have the most frontally placed eyes and the broadest binocular field yet described in birds (type 3 field), and these are thought to be correlated with prey capture using the feet and with the use of auditory cues to locate prey. Owls are unique among birds in having elaborate external ear structures (placed at the edge of the feathers of the facial disk and just behind the eyes), which function to locate sounds accurately, mainly in the region in front of the head. Although owls appear to have forward-facing eyes, the optic axes diverge by nearly 50°, also because the retina does not serve the whole of the available optical field, the degree of binocular overlap appears to be much broader than it functionally is (see Figures 3 and 4). (d) Duck species feed using a range of different foraging techniques. In blue ducks (i, ii) although the eyes are set relatively high in the skull, the visual field shows the typical characteristics of a visually guided forager (type 1 field), but these birds also gain near-comprehensive vision around the head. Blue ducks feed on mobile and sessile prey in fast-flowing mountain rivers and are thought to be visually guided toward individual items. On the other hand, pink-eared ducks (iii, iv) filter feed on small items taken from the surface of often highly turbid waters. In these birds the eyes are set very high on side of the skull and this results in a very narrow area of binocularity that extends from directly in front of the head to directly behind (v), giving the birds comprehensive visual coverage of the hemisphere about the head. However, the birds cannot see their own bill tip, suggesting that bill position does not rely on accurate visual guidance. It is argued that such comprehensive vision is only possible since these birds cannot only feed themselves without relying on visual cues to guide the bill, but also that juvenile birds are precocial and self-feeding and do not need provisioning by the parent, unlike the example of the filter-feeding flamingos that need to provision their young.

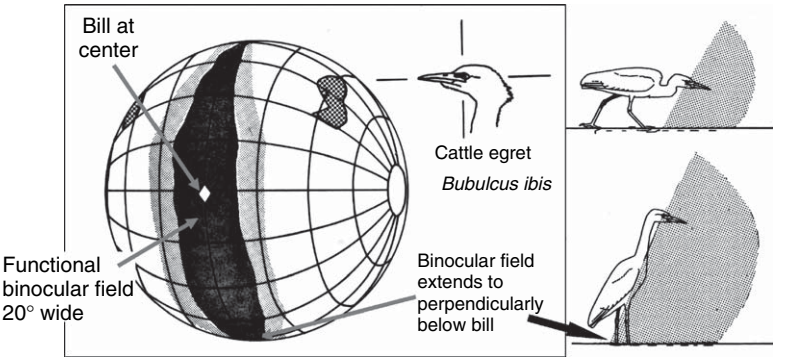


Figure 6 Depiction of visual fields. Example based on data for cattle egret (*Bubulcus ibis*). The diagram shows a perspective view of an orthographic project of the visual field showing the binocular sector that extends from perpendicularly above to perpendicularly below the horizontal plane. The drawings to the right depict postures typical of birds when foraging, and the shading indicates the extent of the binocular field in the in the median sagittal plane. This indicates that the birds can gain extensive visual coverage below the bill, allowing binocular viewing of objects at or close to its feet when the bill is held horizontal.

account for binocularity in birds. Instead it is likely that binocularity is related to the need to analyze optic flow fields (Martin, G. R. and Katzir, G., 1999).

1.03.5.4.1 Binocularity and optic flow fields

The functional importance of binocular overlap may lie not in the fact that each eye can image the same portion of the frontal field simultaneously, but as a result of each monocular field projecting contralaterally. This allows the monocular field to encompass a pole in the linear optic flow field during forward motion (Gibson, J. J., 1986).

Symmetrical flow fields are thought to be important for the control of locomotion in birds, mammals, and insects. The optic flow about a pole gives robust information about the point where the animal is heading, and the time to contact that point (Lee, D. N., 1980; Gibson, J. J., 1986; Davies, M. N. O. and Green, P. R., 1994; Lee, D. N., 1994). Birds need to determine both heading and time to contact rapidly and accurately since they often move at speed toward objects: their heads when pecking, their bodies when approaching objects in flight, and when striking prey with the feet. Flow field variables are known to control landing responses in some, but not all, bird species (Davies, M. N. O. and Green, P. R., 1994). Neurons that respond selectively to various types of flow field, including symmetrically expanding images, are found in the nucleus rotundus (homologue of mammalian pulvinar) of the pigeon forebrain (Frost, B. J. *et al.*, 1994, Sun, H. and Frost, B. J., 1998). These neurons may be functionally equivalent to similar neurons that control self-motion in insects (Krapp, H. G. and Hengstenberg, R., 1996; Srinivasan, M. V., 1996).

In normal forward motion the visual field of an eye must extend contralaterally in order to contain a flow field pole. For forward movement toward a relatively distant target, the disparity of viewpoint of two eyes with overlapping contralateral fields is negligible. The two eyes then should theoretically receive virtually identical optical flow fields, but as the motion signals are likely to be affected by differences in contrast and other image parameters, integration will increase their reliability. Furthermore, for close objects, movement with respect to a target (as in pecking or bill striking) may be precisely specified by the fact that the optic image of the target can be symmetrically positioned with respect to the centers of expansion of each flow field (Lee, D. N. *et al.*, 1991).

Why then is the maximum width of the binocular field in type 1 fields only 20–30°? It can been suggested that this width gives sufficient flow field information for rapid approaches toward objects during foraging, while maximizing the width of the peripheral, and hence cyclopean, visual field (Martin, G. R. and Katzir, G., 1999). In birds such as skimmers, mallard, and woodcocks the binocular overlap at the elevation of the horizontal in flight is only about 10°, which seems sufficient for the control of flight and landing. As mentioned above (see Section 1.03.5.2.1; Figures 3 and 6) in many species the binocular field width could be doubled if full use was made of the optical image. It is interesting that many insects, including flies (Land, M. F. and Eckert, H., 1985), have a binocular overlap of about 10°.

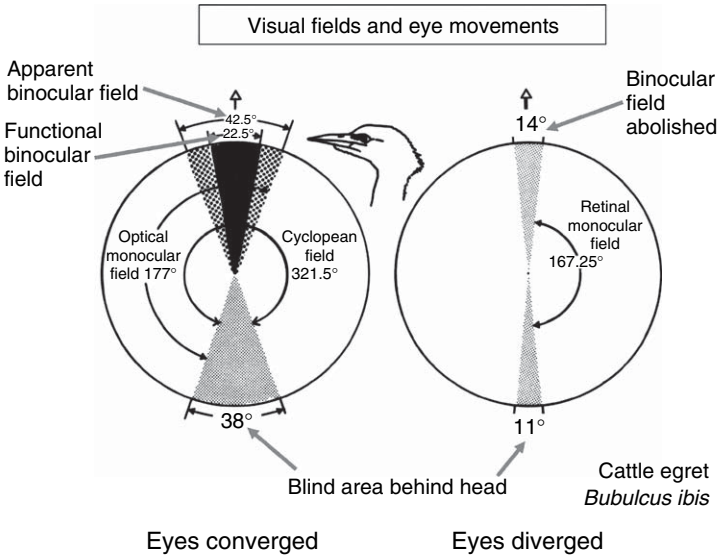

Figure 7 Visual fields and eye movements. Example based on data for cattle egret (*Bubulcus ibis*). Each diagram depicts a section through the visual fields in the horizontal plane. In this plane the margins of the field of each eye can move by up to 18° as a result of eye rotation. When the two eyes are fully rotated to the front of the bird's head (i.e., to the top of the diagram), there is a binocular overlap of 22° (left), but when the eyes are rotated backward, the binocular field is abolished and there is a blind sector 14° wide (right). The eyes can move independently of each other, and therefore, a wide variety of visual field configurations are possible. For example, if one eye is fully forward and the other rotated fully back, then 4° of binocular overlap remains, but this is not symmetrically displaced about the median sagittal plane.

Insects mostly lack stereopsis, and given the importance of optic flow to their flight control (Krapp, H. G. and Hengstenberg, R., 1996; Srinivasan, M. V., 1996), similar reasons may underlie binocularity in insects and birds. As mentioned above (see Section 1.03.5.2.1; Figures 3 and 6) in many species the binocular field width could be doubled if full use was made of the optical image. It is therefore pertinent to consider why the image is not fully used.

In lateral-eyed animals, frontal vision is in fact peripheral vision with respect to the optics of each eye. In all optical systems image quality declines toward the periphery, owing to increases in spherical and other aberrations. There is no information on optical quality in the periphery of any bird eye, but it is a reasonable hypothesis that frontal vision requires the bird to use part of the visual field away from the periphery. No advantage is gained by having contralateral vision to the image periphery since the region that is viewed contralaterally with poor quality optics is covered by more central portions of the ipsilateral eye.

1.03.5.4.2 Binocular vision and nocturnality

The visual fields of owls pose an interesting problem. The wide binocular field described as type 3 (see Section 1.03.5.2.3) has been found only in owls (Figure 5(c)). Broad binocular fields of about 50° have long been associated with the nocturnal and/or the predatory habit of these birds (Walls, G. L., 1942; Tansley, K., 1965). However, similar frontal visual fields are absent in diurnal raptors, such as short-toed snake eagle, which take prey in the feet, or in both flying and flightless nocturnal species such as oilbird (*Steatornis caripensis*), nightjars, night herons, and kiwis. Two factors may account for the particular visual field characteristics of owls: eye size and the use of hearing in the location and capture of prey.

Low light levels favor eyes with a large aperture compared to focal length ratio (i.e., low *f*-number), which produce a bright image but requires a large absolute pupil size to maximize photon catch (Martin, G. R., 1985; Land, M. F. and Nilsson, D.-E., 2002). The consequence of these two requirements is that the eye must be absolutely large, with the attendant costs in mass (see Section 1.03.2). Owl eyes are remarkably long (≈29 mm axial length in tawny owl compared to ≈24.0 mm in human), but their tubular in shape will save weight (Martin, G. R., 1982). If eyes of this length were placed so as to point more laterally, the total skull width would increase greatly; in fact owl eyes protrude more from the skull

than all other birds examined. Eye position therefore may, at least in part, be a matter of the geometry of squeezing a large eye into a small skull.

An additional factor may be associated with the elaborate external ear structures of owls, which function in the accurate sound localization (Payne, R. S., 1971; Konishi, M., 1973; Norberg, R. A., 1978). Owls are unique in the possession of these structures, and they alone may displace the eyes forward in the skull. Furthermore, these large external structures prohibit vision to the rear of the head.

1.03.5.4.3 The blind area above the head and eye size – sunshades in birds

The preceding sections show how the demands of feeding behavior and flight control give a restricted range of frontal binocularity. There is, however, considerable variation in the topography of the total visual field, especially in the extent of the cyclopean field in the horizontal plane and in the width of the blind area above the head (Martin, G. R. and Katzir, G., 2000).

The width of the blind area above the head is a function of eye size (Figures 5(a) and 5(b)). Smaller-eyed birds because of their panoramic vision are unable to avoid imaging the sun, but larger-eyed birds, such as the eagle shown in Figure 3, seem frequently to adopt strategies that avoid imaging the sun. The relationship between eye-size and the width of the blind area may be explained if viewing the sun becomes an increasing problem as eye size increases. The image of the sun can act as a light source within the eye. Scattered light from this image inside the chamber produces the phenomenon that is known in humans as disability glare (Ho, A. and Bilton, S. M., 1986; Dickinson, C. M., 1991) that can prevent target detection, particularly when the original object is of low contrast (Le Claire, J. *et al.*, 1982). In support of this hypothesis is the observation that only in larger-eyed birds are found external structures (eye lashes and enlarged brows, Figure 3(b)) that can shade the eye. The reason why glare is especially problematic for large eyes is not obvious, but it may be that the effects are felt disproportionately in retinae adapted for high resolution. In smaller eyes that have not evolved to achieve the highest resolution, light scattered from an image of the sun upon the retina may not degrade image contrast sufficiently that the benefits of gaining comprehensive visual coverage are outweighed by a reduction in the ability to gain spatial information across the whole of that visual field.

1.03.6 Photoreceptors and the Retina

1.03.6.1 Photopigments and Photoreceptors

Birds have one rod and four types of cone photopigment, which belong to the five ancient genetic families of vertebrate opsins (see Vision in Fish). All have a retinal (A1) chromophore. Spectrophotometric measurements show that the sensitivity maxima (λ_{max}) of four of the five photopigments are conserved across a wide range of avian species, namely, RH1 (λ_{max} 500 nm) that is found in rods, RH2 (λ_{max} 505 nm), SWS2 (λ_{max} 470 nm), and LWS (λ_{max} 565 nm) (fig. 9b; Yokoyama, S. and Yokoyama, R., 1996; Hart, N. S., 2001; Hart, N. S. and Hunt, D. M., 2007). SWS1 pigments fall into two classes according to whether a key site (amino acid 90) has a cysteine or a serine residue, which respectively give λ_{max} values of 365 and 410 nm (Wilkie, S. E. *et al.*, 2000). Spectral sensitivity of SWS1 can therefore be inferred from the opsin DNA, which facilitates the study of the phylogeny (Ödeen, A. and Håstad, O., 2003; Hart, N. S. and Hunt, D. M., 2007). This shows that in birds the 410 nm (VS) variant is the primitive form and that UV sensitivity has evolved independently on at least four occasions (see Section 1.03.6.4).

A penguin (*Spheniscus humboldti*) provides a likely exception to the general uniformity of avian photopigment, with 403, 450, and 543 nm pigments reported (Bowmaker, J. K. and Martin, G. R., 1984). It seems probable that the penguin's LWS pigment is blue shifted and the MWS pigment is absent (see Section 1.03.6.4).

Birds have three morphologically distinct types of photoreceptor: rods, single cones, and double cones (Walls, G. L., 1942; Cserhati, P. *et al.*, 1989). Double cones are widespread in vertebrates (see Vision in Fish; Walls, G. L., 1942), but absent from mammals. Four types of single cone (Figures 8 and 9) are distinguished on the basis of their spectral sensitivity LWS, MWS (containing RH2 pigment), SWS (containing SWS2 pigment), and UV/VS (containing SWS1 pigment and according to whether λ_{max} is near 365 or 410 nm). This nomenclature is potentially confusing because names of cones are similar but do not always match the photopigment. Double cones contain the LWS pigment. Each cone has a specific type of oil droplet in the proximal part of the outer segment (Figures 8 and 9; Bowmaker, J. K., 1977; Cserhati, P. *et al.*, 1989; Hart, N. S., 2001).

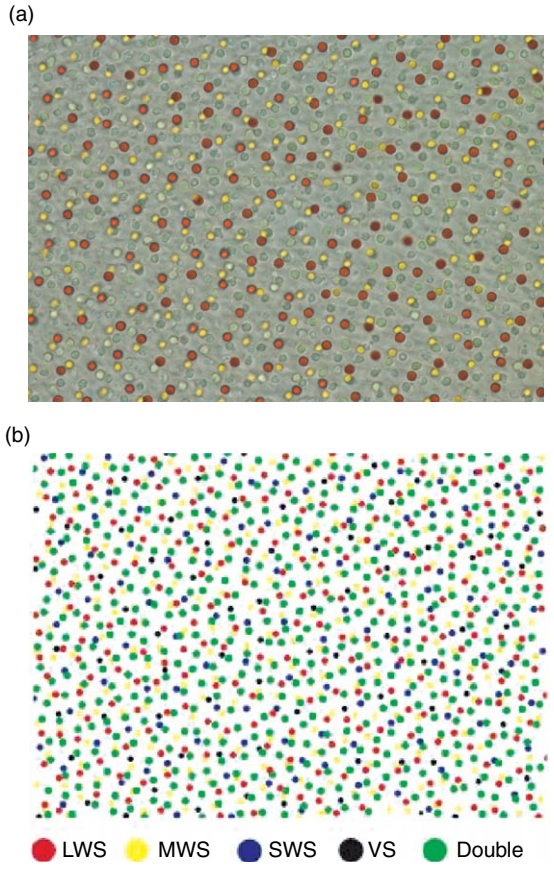

Figure 8 Images of a chicken retina showing the distributions of different cone types as revealed by their oil droplets. (a) Unstained retinal whole mount. Red oil droplets in LWS cones and yellow droplets in the MWS cones are clearly visible. Other types are less readily distinguished in this image but can be identified under UV illumination and by fluorescence. (b) Locations of all five types of cone taken from a different chicken retina. Courtesy of Dr. N. S. Hart.

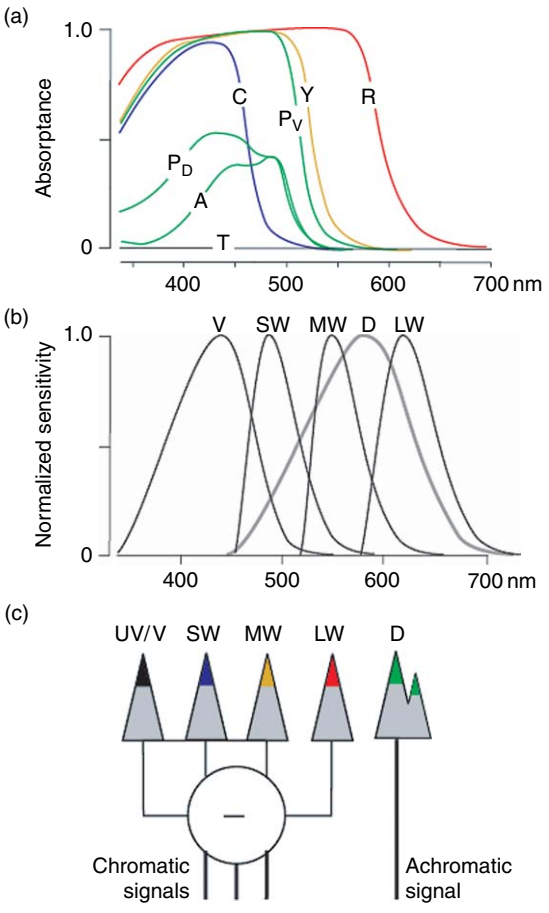

Figure 9 (a) Spectral absorptances of cone oil droplets measured in the peafowl (*Pavo cristatus*) by Hart N. S. (2002). Compare to Figure 8. The droplets are identified as follows: T-type (transparent) in UV/VS cones; C-type (colorless) in SWS cones; Y-type (yellow) in MWS cones, R-type (red) in LWS cones, and P-type (pale) and A-type (accessory) in the principal and accessory members of the double cone pair, respectively. P_V droplets occur in the ventral retina and therefore view the celestial hemisphere. P_D-type droplets occur in the dorsal retina less dense and resemble the A-type droplets. Cutoff wavelengths of the droplets are approximately given as follows: T: none; C: 450 nm; Y: 500 nm; R: 570 nm; P_V: 500 nm in the ventral retina (Hart, N. S., 2002). All these droplets have very high maximum absorbances. The P-type droplets in the dorsal retina and A-type droplets are less dense and cut off at about 480 nm. (b) Photoreceptor spectral sensitivities for a peafowl (Hart, N. S., 2002). The double cone spectral sensitivity curve resembles that of human L cones but will be affected by the specific type of oil droplet present (panel a). These sensitivities represent the primitive state in having a VS (410 nm) pigment. Oscine passerines (other than corvids), parrots, rhea, and gulls have a UVS (360 nm) pigment. (c) Diagram of how two main types of visual signal may be derived from the five types of cone. The four types of single cones serve at least three chromatic mechanisms, while the double cones (D) serve an avian luminance mechanism. Whilst supported by current evidence (see Section 1.03.7), this model may well be elaborated in future.

Spectral filtering by pigmented oil droplets sharpens the tuning of avian LWS, MWS, and SWS cones (Figure 9; Hart, N. S. and Vorobyev, M., 2005). The double cone oil droplet blocks UV, so that the double cone spectral sensitivity resembles that of human L cones. The UV/VS cone oil droplet is transparent. The next section looks further at oil droplets and their pigments.

1.03.6.2 Oil Droplets

Lungfish and many terrestrial vertebrates including marsupials, but not eutherian mammals, have oil droplets in their cone outer segment, which lie immediately proximal to the disks that contain photopigment (Walls,

G. L., 1942; Goldsmith, T. H. *et al.*, 1984; Cserhati, P. *et al.*, 1989). In some vertebrate groups oil droplets are all transparent, and in others, including birds they may be colored (Figures 8 and 9(a)). Where they are colored, oil droplets probably have at least two functions: (1) for focusing (or guiding) light and (2) for spectral filtering. This filtering may be beneficial in excluding damaging UV light and/or for color vision. Direct evidence (e.g., by depleting pigments from oil droplets, Wallman, J. 1979; Bowmaker, J. K. *et al.*, 1993) for the proposed benefits from oil droplets is limited, but there is relevant theoretical work.

The high refractive index of oil droplets compared to cytoplasm suggests a role in focusing or guiding light within the outer segment. The small size (<3 μm diameter) of oil droplets means that waveguide effects are important, so they cannot be understood as a conventional lens (Enoch, J. M., 1980). A physical model using microwaves guided by optics made of plastic (Govardovskii, V. I. *et al.*, 1981) shows that oil droplets can enhance propagation of near-axial rays within the outer segment and reduce the effective intensity off-axis rays. The overall effect is to enhance type I Stiles–Crawford effects (Enoch, J. M., 1980), and hence to reduce the effect of changes in pupil size (see Section 1.03.2.2). Consistent with this finding, a theoretical model suggests that oil droplets may concentrate light within the outer segment (Ives, J. T. *et al.*, 1983).

1.03.6.2.1 Spectral properties of oil droplets and the benefits of narrowing spectral tuning curves

Avian oil droplets contain carotenoids (except for UV/VS cones), which absorb light between the near UV and a longer wavelength (Goldsmith, T. H. *et al.*, 1984). When UV absorption by other optical media is taken into account, the oil droplets act as filters that block short-wavelength light (Hart, N. S. and Vorobyev, M., 2005). One benefit of blocking short wavelengths is to prevent UV photodamage (Young, R. W., 1994). As each cone type has its own specific oil droplet filter, this means that the eye can admit near UV light without damaging longer-wavelength-sensitive receptors. By comparison, mammals are often blind to UV light, because the lens blocks wavelengths below 400 nm. This interpretation is consistent with the relatively low density of pigmentation in double cone oil droplets in the dorsal as compared with the ventral retina of the peafowl (Figure 9(a); Hart, N. S., 2002).

Birds have six types of oil droplets (Figures 8 and 9): T-type (transparent) in UV/VS cones, C-type (colorless) in SWS cones; Y-type (yellow) in MWS cones, R-type (red) in LWS cones, and P-type (pale) and A-type (accessory) in the principal and accessory members of the double cone pair, respectively.

Whereas blocking UV may be the main role of clear double cone oil droplets, in the single cones it seems likely that narrowing and red-shifting spectral sensitivities is important (Figure 9). Thus, LWS cones have a 565 nm visual pigment, but the oil droplet shifts the receptor peak sensitivity (λ_{max}) to around 600 nm; MWS cones have a 500 nm pigment but λ_{max} ~530 nm; and SWS cones a 470 nm pigment and λ_{max} 490 nm. This spectral narrowing has a substantial cost to photon catch (>75% for the LWS cones), and it seems likely that the corresponding benefit is for color vision.

The likely benefits of oil droplets for color vision are, however, not clear. Spectral filtering by oil droplets substantially increases the number of colors (i.e., visual spectra) that theoretically can be discriminated (Vorobyev, M., 2003). Naturally occurring spectra do not, however, occupy the full range of discriminable colors. The advantages are greatest where there is fine detail in the spectra. Some avian plumage colors for example are notably brilliant, and calculations suggest that oil droplets can improve their discriminability compared to unfiltered cone pigments (Vorobyev, M. *et al.*, 1998). However, given the lack of taxonomic variation in oil droplets (see below), and the fact that many groups of birds lack bright plumage, this is not a likely explanation of their primary evolutionary function. Most natural spectra vary smoothly (Maloney, L. T., 1986) in which case the loss of light may more than offset the benefits for color discriminability (Hateren, J. H. van, 1993). An alternative explanation is that narrowing the spectral sensitivity of photoreceptors may be beneficial for color constancy (Worthey, J. A. and Brill, M. H., 1986; Osorio, D. *et al.*, 1997; Vorobyev, M. *et al.*, 1998).

Behavioral tests might resolve questions about the function of oil droplet pigmentation. These are possible because dietary carotenoid deprivation removes oil droplet pigmentation. One study of Japanese quail in optomotor tests shows that effects are consistent, with deprived birds having inferior color vision when compared to normal birds (Wallman, J., 1979).

1.03.6.2.2 Variation in oil droplet pigmentation

In most avian species studied a single type of cone has a single type of oil droplet (Bowmaker, J. K. *et al.*, 1997; Hart, N. S., 2001). However, data are limited,

mainly to passerines and gallinaceous birds. The high refractive index of oil droplets means that it is difficult to measure their absolute optical density, but there is some variation within and between species. As one might expect, pigmentation is relatively weak in nocturnal birds (Hart, N. S., 2001). The wedge-tailed shearwater (*Puffinus pacificus*) has weakly or unpigmented droplets in the high-acuity visual streak dorsal to the equator (and hence in the ventral visual field; Hart, N. S., 2004). Another arrangement that is not unexpected is to have more densely pigmented P-type oil droplets on the double cones in the ventral retina, which views the sky, than the dorsal retina, as is found in the peacock (*Pavo cristatus*; Hart, N. S., 2002). It is likely that such density gradients are at least partly caused by incident light intensity. An experimental study showed that chickens raised in bright illumination have higher pigment density in their oil droplets than do birds raised in dim light (Hart, N. S. *et al.*, 2006).

The most complex retina known is in the pigeon where there are two clearly defined regions: the red sector, which views the ventral–frontal visual field, and presumably is concerned with locating food, and the yellow sector that occupies the remainder of the retina. In the red sector, double cone oil droplets cut off at either about 550 or 525 nm, whereas in the yellow sector, double cone oil droplets cut off between 470 and 500 nm (Bowmaker, J. K., 1977; see also next section).

1.03.6.3 Photoreceptor Densities and Distributions

Receptor densities have been recorded in species including passerines, budgerigar, and chickens, either from oil droplet counts in a retinal whole mount or by spectrophotometry (Figure 8; Hart, N. S. *et al.*, 2000a; Hart, N. S., 2001). Usually 40–50% of the receptors are double cones but range from 30% for pigeon red sector retina to 75% for an owl (*Strix varia*; Bowmaker, J. K., 1977; Braekevelt, C. R. *et al.*, 1996). Of the single cones, LWS and MWS are present in approximately equal numbers and UV/VS least frequent, with SWS densities ranging between these two values (Bowmaker, J. K., 1977; Bowmaker, J. K. *et al.*, 1997; Hart, N. S., 2001). Pigeon yellow sector retina falls within the typical range, with 50% double cones and 12% each of LWS and MWS cones, but the red sector is atypical with 30% double cones and ~25% for each of the LWS and MWS cones (Bowmaker, J. K., 1977). It should be noted that visual thresholds are likely to be proportional to the square root of receptor density (Kelber, A. *et al.*, 2003), so that effects of variations on color vision are relatively small.

Aside from the overall density of the different types of photoreceptor, the layout of the receptor mosaic is of interest, both from a developmental point of view and with regard to retinal sampling. Having six types of receptor poses a problem for spatial sampling because any one type of cone is likely to undersample the image (Snyder, A. W. and Miller, W. H., 1977; Snyder, A. W. *et al.*, 1986). Theory suggests that an orderly cone mosaic, as found in many fish, optimizes coding of spatial information (Lythgoe, J. N., 1979; Bossomaier, T. R. *et al.*, 1985). By comparison, the array of human L and M cones appears to be random (Williams, D. R. and Hofer, H., 2003). It seems possible from published images of retinas that birds are intermediate, they are less orderly than fish, but there is evidence for nonrandom distributions of MWS and LWS cones in starling (Hart, N. S. *et al.*, 2000b). UVS cones in budgerigar are said to be nonrandomly distributed (Wilkie, S. E. *et al.*, 1998).

1.03.6.4 Variation of Receptor Spectral Sensitivities and Densities

It is readily apparent that avian visual optics vary between species and that often this variation reflects visual ecology (see Sections 1.03.2, 1.03.3, and 1.03.5). By comparison, it seems that spectral sensitivities of avian photoreceptors are conservative with little evidence for adaptive variation (Hart, N. S., 2001; Hart, N. S. and Hunt, D. M., 2007). Thus, a strictly marine bird the wedge-tailed shearwater has very similar spectral receptors to a peacock (Hart, N. S., 2002; 2004). There are, however, some exceptions.

First, humboldt penguin (*S. humboldti*) probably has only three types of visual photopigment, with 80% double cones and probably three types of single cone. Pigment sensitivity maxima are at 403, 450, and 543 nm, and the longest wavelength oil droplet cuts off below 525 nm (Bowmaker, J. K. and Martin, G. R., 1984; Suburo, A. M. and Scolaro, J. A., 1999). It seems likely that this eye reflects the lack of long wavelengths in water.

A more widespread mode of variation is in the spectral sensitivity of the SWS1 pigment. As mentioned above (see Section 1.03.6.1), there are two main forms of this pigment with sensitivity maxima

at about 365 nm (UV) and 410 nm (VS). The UV form occurs in most oscine passerines (but not corvids), in a gull (*Larus* sp.), ostrich (but not rhea (*Rhea Americana*)), and parrots (Psittaciformes). The VS form is found in the suboscine and corvid groups of passerines, and most other avian lineages (Ödeen, A. and Håstad, O., 2003). That there may be adaptive variation in the spectral tuning of the UV/VS cones is perhaps not surprising as theoretical considerations suggest that small shifts in the spectral composition and intensity of illumination will affect the relative merits of these two types of pigment (Vorobyev, M. *et al*., 1998). There is, however, no obvious explanation for the observed pattern of variation.

1.03.7 Functions of the Different Types of Avian Cone

Given that birds have five types of cone photoreceptor, it may be that receptors are specialized for particular behaviors, or aspects of visual perception. Identification of visual pathways is a key aspect of work on primate vision. Here a familiar distinction is between the magnocellular pathway, originating from the parasol-type retinal ganglion cells, and the parvocellular pathway originating from the midget retinal ganglion cells (Kaplan, E., 2003). Regarding the evolutionary basis for the presence of separate visual pathways, an obvious question is whether the functional divisions are specific to particular groups, such as primates, or have emerged separately in separate lineages: that is, by convergent evolution. As predominantly diurnal and arboreal animals, primates are in many ways the most bird-like of mammals, so that comparisons are of particular interest.

The primate magnocellular system combines M (green) and L (red) cone outputs to give a luminance signal, which is used for motion and many aspects of form recognition (Livingstone, M. and Hubel, D., 1988; Kaiser, P. K. *et al*., 1990; Logothetis, N. K., *et al*., 1990). The magnocellular system signal has relatively high contrast sensitivity, but spatial resolution is limited by spatial pooling of cone outputs in the parasol ganglion cells (Kaplan, E., 2003). By comparison, the parvocellular system has relatively low contrast sensitivity, but midget ganglion cells do not pool cone outputs (at least in the central visual field). This system can encode high spatial frequencies and the red–green chromatic signal, which is based on spectral opponency between L and M cone signals. Further types of primate retinal ganglion cell encode S (blue) cone signals including blue–yellow opponent signals (Dacey, D., 2000).

There is little work on physiology of avian retinal ganglion cells, but there are studies of specialization of the cone photoreceptors themselves. Starting from receptor spectral sensitivities (Hart, N. S., 2001), one can use stimuli that give well-specified receptor excitations and so isolate subsets of receptors (Osorio, D. *et al*., 1999a; 1999b; Goldsmith, T. H. and Butler, B. K., 2003; 2005). The emerging picture suggests that the double cones have a role comparable to that of the primate M-cell pathway. They provide an avian luminance signal, which is used for motion detection and certain aspects of form vision (Campenhausen, M. von and Kirschfeld, K. 1998; Osorio, D. *et al*., 1999b; Jones, C. D. and Osorio, D., 2004; Goldsmith, T. H. and Butler, B. K., 2005). Avian single cones are used for color vision, and birds may have a tetrachromatic color vision based on the four single cones. The following sections review the evidence for functional specialization of the avian cones.

1.03.7.1 Double Cones and Avian Luminance

In human psychophysics techniques such as the minimally distinct border are used to determine the spectral sensitivity of visual mechanisms. The relative brightness of two colors regions is adjusted until a sensitivity minimum or null is reached (Kaiser, P. K., 1971; Livingstone, M. and Hubel, D., 1988; Kaiser, P. K. *et al*., 1990). This establishes that certain visual tasks are predominately color-blind (i.e., they do not use chromatic signals) and shows that the achromatic signal that is used has the spectral sensitivity characteristic of the luminance mechanism or M-cell system (see Section 1.03.7).

In birds nulling techniques have been used with optokinetic responses (i.e., motion perception), in quail and pigeons (Wallman, J., 1979; Campenhausen, M. von and Kirschfeld, K., 1998), and with texture perception in poultry chicks (Jones, C. D. and Osorio, D., 2004). There are also comparable studies of spectral inputs to motion-sensitive neurons in pigeons (Sun, H. and Frost, B. J., 1997). These studies generally suggest that the tasks in question is color blind, but Wallman J. (1979) gives evidence for a chromatic input to optokinetic responses in quail (*Coturnix coturnix*). Also, the spectral sensitivity resembles that of the double cones and is unlikely

to be attributable to any one type of single cone (Osorio, D. *et al*., 1999b; Jones, C. D. and Osorio, D., 2004). A single measurement of spectral sensitivity does not, however, readily distinguish a mechanism that combines an appropriately weighted sum of single cone outputs from a double cone signal. A distinction could be made by tests of the effects of selective adaptation, but to our knowledge this has not been done.

The notion that the double cones give an avian luminance signal is reinforced by evidence that they do not contribute to color vision, which we outline in the following section.

1.03.7.2 Single Cones and Tetrachromacy

The narrow spectral tuning of the single cones (Figure 9), and their comparatively even spacing across the spectrum, indicates that they are adapted for coding spectral information, and hence for color vision. Color vision requires comparison of the outputs for two or more spectral types of receptor. For a range of species there is evidence that color vision is served by chromatic mechanisms, with low sensitivity to brightness (Vorobyev, M. and Osorio, D., 1998; Kelber, A. *et al*., 2003). Also we know that humans are trichromatic, in that signals from each of the three cone types are used independently so that spectra are coded with three degrees of freedom. However, within the 3D human color space the two dimensions that represent chromaticity (i.e., hue and saturation) appear to be more relevant to color perception than the achromatic axis (brightness). This is why 2D chromaticity diagrams, such as the CIE *xy* color triangle, that represent a gamut of colors of approximately equal brightness proves useful.

By analogy with human trichromatic color vision, it is a plausible hypothesis that birds are tetrachromatic. Within the 4D avian color space one can plot a 3D chromatic tetrahedron, which is analogous to a human color triangle (Goldsmith, T. H., 1990; Kelber, A. *et al*., 2003). Tests of tetrachromacy are, however, elusive. The key prediction is that two lights of differing spectral composition will have the same color (i.e., they are metamers) only if each of the receptor mechanisms (i.e., cone types) gives the same response to each of the two lights. A mismatch in one mechanism could not be offset by a complementary adjustment to another. It should be noted that the receptor mechanisms used may be contingent on a number of factors, such as the illumination level, the visual task, and the visual field used. There is no *a priori* reason for having a single type of color vision.

Behavioral investigation of color vision benefits from the knowledge of receptor spectral sensitivities, and these are now available for many bird species (see Section 1.03.6; Hart, N. S., 2001; Hart, N. S. and Hunt, D. M., 2007). Two principal methods are used to investigate receptor inputs to avian color vision, both of which support the view (Goldsmith, T. H., 1990) that birds use four single cones to give tetrachromatic color vision. Direct but inconclusive evidence comes from studies that isolate specific subsets of receptors by combinations of illumination and reflectance spectra (Osorio, D. *et al*., 1999b). This method can show whether birds have specific chromatic mechanisms. Thus, week-old poultry chicks probably have at least three opponent mechanisms: L versus M, L+M versus S, and S versus VS (Osorio, D. *et al*., 1999b). Separate evidence from studies with spectra that differ only in the UV suggests that VS/UV receptors contribute to color vision of starling and quail (Smith, E. L. *et al*., 2002). These studies give evidence for tetrachromacy but are not conclusive and do not rule out a role for the double cones.

Clear, if less direct, evidence for tetrachromacy comes from spectral sensitivity data for pigeon, budgerigar (*Melopsittacus undulatus*), and a passerine (Pekin robin, *Leiothrix lutea*; Vorobyev, M. and Osorio, D., 1998; Goldsmith, T. H. and Butler, B. K., 2003; 2005). In tests of spectral sensitivity subjects discriminate between two stimuli: a uniform adapting field, which is approximately achromatic, and a field where monochromatic light is added to a central region (and so appears nonuniform). The procedure gives the minimum intensity of a given wavelength that is detectable against the background, and when tests are repeated across the spectrum they generate a spectral sensitivity curve. Under light-adapted conditions, spectral sensitivities for a wide range of animals, including birds, are consistent with a model where discrimination thresholds are set by chromatic (i.e., opponent) signals derived from single cone mechanisms, achromatic mechanisms are much less sensitive, and there is no evidence for a role for double cones (Vorobyev, M. and Osorio, D., 1998; Goldsmith, T. H. and Butler, B. K., 2003; Kelber, A. *et al*., 2003; Goldsmith, T. H. and Butler, B. K., 2005). This model does not predict visual thresholds for Pekin robin in low light conditions, or for the pigeon red field, where achromatic signals appear to be more important in setting spectral sensitivity thresholds.

1.03.7.3 Specialization of Single Cones and UV Sensitivity

Aside from their role in color vision, one can ask whether a given sensory receptor contributes to specific behavior. In birds particular attention is given to UV/VS cones. In part this work is stimulated by the interest in the idea that birds perceive the world in a way different from ourselves. More specifically, there is evidence that plumage that is used in visual displays reflects more strongly in the UV than do other types of plumage (Hausmann, F. *et al*., 2003). By filtering illumination, and by the using UV blocking filters (i.e., sunblock) painted on plumage, it can be shown that UV wavelengths are used in courtship behavior and foraging behaviors (Cuthill, I. C., 2006). For example, the attractiveness of male starlings and zebra finches to females is altered according to whether or not the UV is in the illumination (Bennett, A. T. D., *et al*., 1996; 1997), and the attractiveness of male bluethroats (*Luscinia svecica*) is reduced by blocking UV reflectance from their blue throat patches (Andersson, S. and Amundsen, T., 1997). These findings are of interest, in part because there is great variation in the proportion of UV in natural illumination, and so have implications for how male birds select display sites. There is, however, no clear evidence that the UV signal is of special significance compared to those from the other single cones. It would be interesting to know whether the UV signal is perceived as an aspect of chromaticity or brightness.

1.03.8 Concluding Remarks: A Wing Guided by an Eye?

This chapter opened with the phrase, "A bird is a wing guided by an eye," coined by Rochon-Duvigneaud A. (1943) to capture the essence of a bird. The discussion that followed shows clearly that birds use their eyes for far more than the guidance of flight and that some birds do not use their eyes to guide flight. The discussion also showed that although some general principles regarding the optical structure of eyes can be discerned, and rules regarding the form and function of visual fields have been proposed. The study of bird eyes presents many challenges, which are met by a number of techniques and approaches, but key among them are comparative studies that relate eye design to ecology and behavior. It is sobering to note that aspects of eye structure and/or visual fields are discussed for <1% of all bird species currently recognized. Each species represents an independently evolving lineage, in which vision is likely to have become finely tuned by natural selection to the challenges presented by the ecology and behavior of the species. We have some idea of the general principles that have governed the design of eyes and their placement in the skull, but we are far from knowing the subtle variations that natural selection has built around these general designs.

Glossary

Actinopterygii A vertebrate class including all the rayed-finned fish.

agnathostomes Primitive jawless fish represented today by lamprey and hagfish.

apoptosis Programmed cell death where a series of biochemical processes lead to characteristic changes in cell morphology and cell death.

chondrostei Primitive rayed-finned cartilaginous fish showing some ossification, including sturgeons and paddlefish.

elasmobranchs Cartilaginous fish including sharks, skates, and rays.

flexion in larval fish A developmental stage when there is a bending upward of the notochord tip as part of the process of caudal-fin formation.

gnathostomes Jawed vertebrates.

holostei Primitive bony fish including bowfins and garfish.

microspectrophotometry A technique in which a narrow beam of light is passed through an isolated rod or cone in order to measure the absorption of the visual pigment.

notochord A flexible, rod-shaped body found in embryos against which the body muscles act and replaced in adults by the vertebral column.

ontogeny The study of the origin and the development of an organism from the fertilized egg to its adult form.

phylogeny The study of evolutionary relatedness among various groups of organisms.

porphyropsins All visual pigments based on Vitamin A_2.

pseudogene A region of DNA that can be recognised as a gene or part of a gene, but has lost protein-coding ability or is otherwise no longer expressed in the cell.
rhodopsins All visual pigments based on Vitamin A_1.
Sarcopterygii A vertebrate class including the lobed-finned fish (coelacanths and lungfish) and all terrestrial vertebrates.
teleosts All 'modern' bony fish, but excluding the primitive chondrosteans and holosteans.

1.04.1 Introduction

About half of all living vertebrates are fish and the vast majority of these are teleosts. Perhaps surprisingly, freshwater fish make up about 40% of total fish species, yet rivers and lakes make up less than 1% of the earth's water. The remaining 60% of fish species occupy marine environments, though the oceans comprise about 97% of all the water on earth (Horn, M. H., 1972). This implies that freshwaters offer much greater opportunities for speciation with a wide variety of habitats and the possibility of population isolation in contrast to the rather more uniform open ocean. This is not to deny the great variation in coastal waters and coral reefs, and the major changes that occur with depth in the ocean, not generally available to freshwater fish.

These great variations in spacelight in the aquatic environment offer a singular prospect for studying the evolution of color vision in vertebrates. Water color in the seas can vary from clear blue oceanic water to green coastal waters, and freshwaters show an even wider range of colors due to dissolved organic material (DOM), ranging from clear blue lake waters through to heavily peat-stained brown river waters. This broad range of aquatic habitats has led to many variations in the visual system of fish, notably in the arrangement and variety of rod and cone photoreceptors in the retina. The cone complement of fish retinas is highly variable, with species possessing cones from a single spectral class to others possessing four or more spectrally distinct classes. In addition, different morphological types of cone are present, with at least two types of single cone, and double cones in which the two halves may be spectrally identical or spectrally different.

There have been many recent reviews of vision in fish, focused primarily on teleosts (see Douglas, R. H. and Djamgoz, M. B. A., 1990; Bowmaker, J. K., 1995; Partridge, J. C. and Cummings, M. E., 1999; Douglas, R. H., 2001; Marshall, N. J. *et al.*, 2003; Bowmaker, J. K. and Hunt, D. M., 2006; Hunt, D. M. and Bowmaker, J. K., 2006; Partridge, J. C. *et al.*, 2006). The aim of this chapter is to highlight some of the recent advances in our understanding of fish vision and visual pigments, concentrating on the evolutionary consequences of opsin gene duplication and the presence of multiple cone pigments and how this is reflected in the changes in visual sensitivity observed in many teleosts during development. Recently there has also been an increased interest in the visual pigments and visual capabilities of the more primitive fish groups such as lamprey and sturgeon, as well as in the living fossils, coelacanths, and lungfish.

1.04.2 Evolutionary Origin of Visual Pigments

Comparative studies across all of the major vertebrate groups have established that, in addition to a rod class of pigment, there are four spectrally distinct classes of cone pigment encoded by distinct opsin genes: a long- to middle-wave class (LWS) maximally sensitive in the red–green spectral region from about 490 to 570 nm, a middle-wave class (Rh2) sensitive in the green from about 480 to 535 nm, a short-wave class (SWS2) sensitive in the blue–violet from about 410 to 490 nm, and a second short-wave class (SWS1) sensitive in the violet–ultraviolet from about 355 to 440 nm (Yokoyama, S., 2000). These cone classes have arisen through a series of gene duplications from an ancestral single opsin gene. By applying estimates of the rate of gene divergence, it is suggested that the appearance of the four classes occurred very early in vertebrate evolution, about 450–500 million years ago (MYA). This is close to the time of one of the major steps in vertebrate evolution, the appearance of jaws.

1.04.3 Lamprey

Primitive jawless fish, agnaths, are represented today by lampreys and hagfish. Studies of the northern hemisphere lampreys (*Petromyzon* and *Lampetra* spp.) have established that these species contain only two classes of photoreceptor classified as rods with a single class of cone maximally sensitive at longer wavelengths (Govardovskii, V. I. and Lychakov, D. V., 1984; Ishikawa, M. *et al.*, 1987; Negishi, K. *et al.*, 1987; Hárosi, F. I. and Kleinschmidt, J., 1993). Electrophysiological data suggest that the rods may function at both scotopic and photopic levels (Govardovskii, V. I. and Lychakov, D. V., 1984). In the southern hemisphere species, *Mordacia mordax*, only a single class of rod photoreceptor has been identified (Collin, S. P. *et al.*, 2004).

In contrast to these species with limited photoreceptor classes, the southern hemisphere species, *Geotria australis*, in addition to rods, has multiple spectral classes of cone (Collin, S. P. *et al.*, 2003a). Microspectrophotometry (MSP) has identified two spectrally distinct classes of cones containing porphyropsins with a wavelength of maximum absorbance, λ_{max}, at about 610 and 515 nm, along with rods with λ_{max} at about 505 nm. Further study of the genetic complement of visual pigment opsins in *Geotria* (Collin, S. P. *et al.*, 2003b) has identified five opsin genes. Three of these are orthologous to the LWS, SWS2, and SWS1 opsin genes of jawed vertebrates, but the remaining two, RhA and RhB, appear to be equally distantly related to the gnathostome Rh1 and Rh2 gene families. Collin S. P. *et al.* (2003b) proposed that the gene duplication that gave rise to the true rod Rh1 gene and the middle-wave-sensitive cone Rh2 gene of jawed vertebrates occurred after the separation of the gnathostomes from the agnaths. However, this assertion has been questioned (Collin, S. P. and Trezise, A. E. O., 2006; Pisani, D. *et al.*, 2006), with further phylogenetic analyses suggesting that the RhA lamprey gene is orthologous to the Rh1 gene (Figure 1).

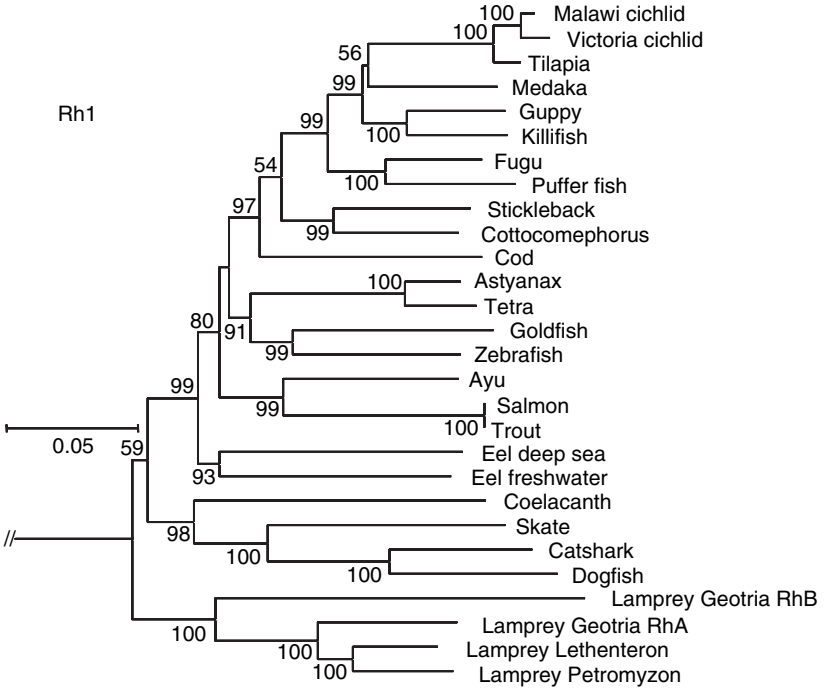

Figure 1 Phylogeny of teleost's Rh1 (rod) opsin genes. Nucleotide sequences were aligned by ClustalW, and the tree was generated by the neighbor-joining method (Saitou, N. and Nei, M., 1987). The bootstrap confidence values (1000 replicates) are shown for each branch. The *Drosophila* Rh4 sequence (M17719) was used as an outgroup (not shown). The scale bar is equal to 0.05 substitutions per site. Sequences were obtained from GenBank accession numbers AY775114, AY673768, AY775108, AB180742, Y11147, AY296738, AF201471, CR704557, BT028623, U97266, AF385832, U12328, AB245433, L11863, AF109368, AB086404, AF201470, AF201470, L78008, L78007, AF131253, U81514, Y17585, Y17586, AY366494, AY366493, AB116382, U67123.

The status of the lamprey RhB gene is less clear. The debate about the evolution of rod opsins and scotopic vision will continue, and it raises the intriguing question as to what defines a rod and a cone and also how to classify the photoreceptors in lampreys that contain the RhA and RhB opsins. Are these cell types defined by their opsin content, the isoforms of the proteins involved in visual transduction, or the physiological parameters of excitation and adaptation?

1.04.4 Rays and Sharks

Although traditionally elasmobranchs were thought to be primarily adapted for scotopic vision in having an all-rod retina (Walls, G. L., 1942), their phylogenetic position, radiating early (about 400 MYA) from the main gnathostome lineage, would imply that they have the potential of retaining all of the four vertebrate cone opsin classes. Indeed, it is clear that most, if not all, sharks and rays possess at least a single class of cone (Cohen, J. L., 1990), as is the case for the guitarfish, *Rhinobatos lentiginosus,* where MSP found a single spectral class of cone with a λ_{max} identical to that of the rod (Gruber, S. H. *et al.*, 1990). However, some skates may have pure rod retinas (Ripps, H. and Dowling, J. E., 1990; Govardovskii, V. I. and Lychakov, L. V., 1977) and in two species of *Raja*, the rods function at both scotopic and photopic levels (Dowling, J. E. and Ripps, H., 1990; Ripps, H., and Dowling, J. E., 1990), superficially similar to the rods of northern hemisphere lamprey (Govardovskii, V. I. and Lychakov, L. V., 1984).

In contrast, electroretinography from the retina of the common sting ray, *Dasyatis pastinaca* (Govardovskii, V. I. and Lychakov, L. V., 1977), revealed a spectral sensitivity with three peaks, suggesting cone visual pigments with λ_{max} at 476, 502, and 540 nm. Further, studies of horizontal cells from a related species, the red stingray *Dasyatis akajei* (Toyoda, J. I. *et al.*, 1978), identified three layers of horizontal cells in which the innermost layer consisted of chromatically coded C-type cells. More recently, MSP studies have demonstrated that two species of shovelnose rays (*Rhinobatos typus* and *Aptychotrema rostrata*) (Hart, N. S. *et al.*, 2004) and the blue-spotted maskray, *Dasyatis kuhlii* (Theiss, S. M. *et al.*, 2007), possess three spectral classes of single cone with λ_{max} at about 460–480, 490–500, and 550–560 nm. All three species have rods with λ_{max} close to 500 nm. These data clearly suggest that these species of ray have at least a trichromatic color vision system.

1.04.5 Chondrosteans/ Acipenseriformes

This ancient order of ray-finned fish consists of 25 species in two families, the sturgeons (Acipenseridae) and the paddlefish (Polyodontidae). The retinas of all but a single species of sturgeon and paddlefish contain rods and single cones with no evidence of paired elements (the stellate sturgeon is all cone; Govardovskii, V. I. and Zueva, L. V., 1987). Within a species there is little morphological difference between cones shown by MSP to contain different visual pigments (see below). Interestingly, all of the cones have a colorless oil droplet although there is a report of a small cone without a droplet in the Siberian sturgeon (Govardovskii, V. I. *et al.*, 1991).

All knowledge of the cone visual pigments in these groups comes from MSP (for a recent review, see Sillman, A. J. and Dahlin, D. A., 2004). From the position of the λ_{max}, it appears that the adults express at least one LWS, Rh2, and SWS2 gene in individual cones, in addition to an Rh1 gene in the rods. In the absence of genomic data it is uncertain how many Rh2 or SWS2 genes there are, but the lack of appreciable variability within each spectral group suggests that if there were multiple genes being expressed, they are isochromatic or at least differ little in the visual pigment they yield.

In freshwater, most adult sturgeon and paddlefish are bottom feeders quite at home in dim, muddy, highly turbid environments. For this reason, and their relatively small eyes and documented highly developed sense of smell, it is surprising to find that these species have retained such an apparently complex potential color vision capability.

1.04.6 Holosteans

These primitive fish, diverging from the chondrosteans about 250–300 MYA, were dominant in both marine and freshwater environments in the Triassic some 200 MYA. However, only two surviving genera, both inhabiting freshwaters in North America, have survived. The Amiidae have a single surviving representative, the bowfin *Amia calva.* The Lepisosteidae are the gars with seven surviving species.

No opsin data are available for either of these groups; however, some inferences can be drawn

from MSP data. In *Amia*, Burkhardt D. A. *et al.* (1983) identified double cones containing pigments with λ_{max} at 624 nm and 556 nm and single cones with λ_{max} at 457 nm, the pigments best fit by Vitamin A_2 visual pigment templates. This suggests the expression of LWS, Rh2, and SWS2 opsins. Only adult individuals were examined and no data on the presence or absence of an SWS1 gene are available.

The longnose gar, *Lepisosteus osseus*, has the full complement of opsin group expression even in the adult. Previously only two classes of cone pigment had been reported with λ_{max} at about 623 and 535 nm (Levine, J. S. and MacNichol, E. F., 1979; Burkhardt D. A. *et al.*, 1983), presumably representing LWS and Rh2 cone classes, but a recent MSP study of adult longnose gar (Loew, E. R., unpublished observations) identified five cone pigments with λ_{max} at 631, 541, 441, 427, and 365 nm. These most likely represent expression of LWS, Rh2, SWS2, and SWS1 opsin groups. Of particular interest is the presence of what could be the expression of two SWS2 genes (the 427 and 441 nm pigments) suggesting an early gene duplication (see below).

1.04.7 Lungfish and Coelacanth

The exact phylogenetic relationship between lungfish (Dipnoi), coelacanths (Crossopterygei, Coelacanthimorpha), and tetrapods remains unclear (e.g., Thomson, K. S., 1993; Meyer, A., 1995), but lungfish and coelacanths occupy a unique evolutionary link between terrestrial vertebrates such as reptiles and birds, and aquatic vertebrates such as teleosts and elasmobranchs. These groups diverged in the early Devonian about 350–400 MYA.

There are only three extant species of lungfish, geographically separated in Australia, South America, and Africa. The retinal organization of the Australian species, *Neoceratodus forsteri*, has recently been studied in some detail. The retina contains, in addition to rods, multiple classes of cones distinguished by brightly colored oil droplets (Robinson, S. R., 1994; Bailes, H. J. *et al.*, 2006), a feature common to reptiles and birds. At least three morphologically distinct cone classes can be identified: about 75% with a large red droplet, about 15% with a yellow pigmented ellipsoid region, and about 5% with a small clear droplet (Figure 2). This strongly suggests that *N.*

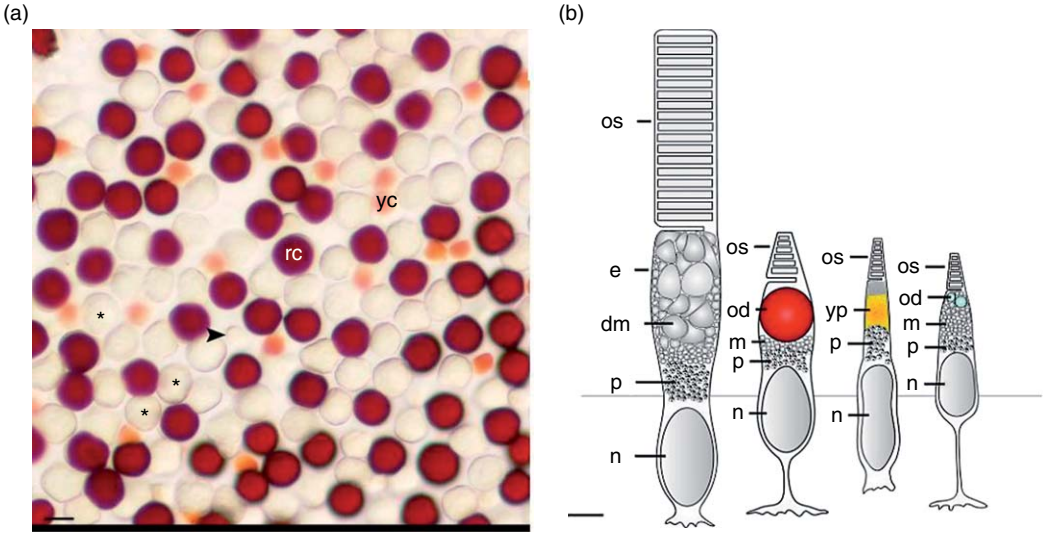

Figure 2 Photoreceptors of the Australian lungfish, *Neoceratodus forsteri*. (a) Retinal wholemount of a fresh retina showing all four morphological photoreceptor types at the level of the ellipsoid. The large, clear photoreceptors (asterisks) are rods; the red (rc) and yellow (yc) cones are easily distinguishable by the color of their intracellular inclusions. One clear cone (arrowhead) can be identified because it is noticeably smaller than the rod photoreceptors. (b) Schematic summary of photoreceptor types drawn to scale. dm, distended mitochondria; e, ellipsosome; m, mitochondria; n, nucleus; od, oil droplet; os, outer segment; p, paraboloid; yp, yellow pigment. Scale bars = 10 μm. Reproduced from Bailes, H. J., Robinson, S. R., Trezise, A. E. O., and Collin, S. P. 2006. Morphology, characterization, and distribution of retinal photoreceptors in the Australian lungfish *Neoceratodus forsteri* (Krefft, 1870). J. Comp. Neurol. 494, 381–397, with permission from John Wiley & Sons Ltd.

forsteri has the potential for at least trichromatic color vision and recent analysis of visual pigments by MSP (Marshall, J. *et al.*, 2006a) has identified four spectrally distinct cone pigments in addition to a rod pigment. In adults, three porphyropsin cone pigments are present with λ_{max} at 479, 557, and 620 nm, whereas young fish have an additional UV-sensitive cone pigment with λ_{max} at 374 nm. The Australian lungfish has therefore retained the four vertebrate ancestral cone pigments with the potential for tetrachromatic color vision, at least at a juvenile stage. The presence of the colored oil droplets also implies that this feature is ancient and may represent the ancestral composition of cones (Walls, G. L., 1942; Robinson, S. R., 1994). Morphologically different cone classes may also be present in the African and South American lungfish (Walls, G. L., 1942; Ali, M. A. and Anctil, M., 1973), but their spectral properties have not been examined.

In contrast to lungfish that live in shallow freshwater rivers, the two extant species of coelacanth are found in relatively deep waters between 100 and 400 m in the Indian Ocean. Their retinae are more typical of deep-sea fish and are rod-dominated with cones comprising only about 1–2% of the photoreceptors (Millot, J. and Carasso, N., 1955; Locket, N. A., 1973). However, these may possibly be divided into three morphological classes. The rarest cone class (type 1 of Locket), with only about 22 mm^{-2}, contains an oil droplet that is probably colorless (Millot, J. and Carasso, N., 1955). The extracted rod pigment with λ_{max} at 473 nm (Dartnall, H. J. A., 1972) is typical of deep-sea fish and its sensitivity may be correlated with the maximum transmission of oceanic water, around 470–480 nm. Recently two opsin genes have been isolated from both species of *Latimeria* (Yokoyama, S. *et al.*, 1999; Yokoyama, S. and Tada, T., 2000.), which are orthologous to the Rh1 and Rh2 vertebrate opsins. These genes have been expressed and have λ_{max} at 485 and 478 nm, respectively. Yokoyama S. *et al.* (1999) also isolated a pseudogene derived from the SWS1 class, but no evidence was found for either an LWS or a SWS2 gene. Yokoyama S. *et al.* (1999) suggested that because of their spectral closeness, the 473 nm pigment extracted by Dartnall H. J. A. (1972) was in fact the Rh2 pigment, but this cannot be the case. Extraction techniques typically yield only rod pigments and given the very low numbers of cones in the retina of *Latimeria*, the extracted 473 nm pigment must be the Rh1 pigment, which has λ_{max} at 485 nm when expressed. The 12 nm discrepancy between the two values is surprising, given that extracts of rod pigments from deep-sea fish typically agree with direct measurements of visual pigment absorbance by MSP. It has also been suggested (Yokoyama, S. *et al.*, 1999) that the presence of the Rh1 and Rh2 pigments could give the coelacanth rod-/cone-based color vision within the narrow spectral window available at depth in the ocean. Given the very low density of cones, this seems an unlikely scenario and it is more probable that the cones will give a very limited luminance response at photopic levels.

The two extant species of coelacanth are nocturnal piscivorous predators living at depth in the ocean (Fricke, H. and Hissmann, K., 2000), but their Devonian ancestors likely lived in a coastal wetland environment (Thomson, K. S., 1993) and presumably possessed a typical vertebrate polychromatic photopic visual system. Comparisons of the Rh1 and Rh2 opsin genes from both coelacanth species suggest that the migration to the deep sea occurred about 200 MYA (Yokoyama, S. and Tada, T., 2000). The change in habitat to the relatively dim monochromatic deep sea presumably resulted in the loss of color vision along with the loss of function of the other three cone opsin genes.

1.04.8 Teleosts

The numbers of teleost species far exceed those of any other fish group and comprise about 96% of all living fish species. The teleost radiation began in the Cretaceous about 150 MYA and by the end of the Cretaceous, it had become the dominant fish in both oceanic and freshwater habitats. Teleost vision ranges from tetrachromatic color vision in many shallow water freshwater fish to pure rod vision in the majority of deep-sea fish. Adult epipelagic teleosts tend to be trichromatic or dichromatic, having lost or no longer expressing either the LWS or the SWS1 opsins or both. In contrast, fish living in highly turbid or deeply stained waters tend to lose or not express the shorter-wave opsins, but retain the LWS and Rh2 opsin genes. In more extreme conditions, fish may become cone monochromats expressing only the Rh2 or LWS genes.

1.04.8.1 Multiple Opsins

Unlike most other vertebrate groups, many teleost families have duplicated their cone opsin genes to produce a range of functional opsins within each

opsin gene class. There is evidence that the Actinopterygii (ray-finned fish) have more genes than other vertebrate groups and it has been suggested that a whole-genome duplication occurred early in the evolution of ray-finned fish, in the Devonian around 350 MYA, after their divergence from the sarcopterygian lineage (Meye, A. R. and Schartl, M., 1999; Christoffels, A. *et al.*, 2004; Furutani-Seiki, M. and Wittbrodt, A. V., 2004). Thus the sarcopterygian fish, which includes coelacanth and lungfish, and all land vertebrates (amphibians, reptiles, birds, and mammals), tend to have only half the number of genes compared with actinopterygian fish. However, the evolution of gene families is an active process in which gene duplication (whether by whole-genome duplication or simple duplication of a limited number of genes) will be accompanied by the subsequent mutation of genes, leading either to the decay of some genes into pseudogenes and eventually junk DNA or to a divergent gene with a new function (neofunctionalization) (Ohno, S., 1970). In groups such as cichlids and cyprinids, mutations in the duplicated genes have led to functional spectral shifts in the pigments, but at least in puffer fish (tetraodontids) there is evidence that one of their duplicated Rh2 genes is a pseudogene that has suffered a loss of function relatively recently (Neafsey, D. E. and Hartl, D. L., 2005). Gene duplication in teleost opsin genes is most notable within the Rh2 gene family, but also occurs in both the LWS and SWS2 classes. Evidence for duplication of the SWS1 gene is limited and has been reported only in the ayu (*Plecoglossus altivelis*, an osmerid salmonid) (Minamoto, T. and Shimizu, I., 2005).

1.04.8.2 Rh2 (Middle-Wave Green-Sensitive) Opsin Duplication

One of the most striking examples of opsin gene duplication is found in the cichlid populations of the African Great Lakes. These species are notable for their diversity, particularly in their color patterns. Lake Malawi has more than 700 species of cichlids that have evolved from a common ancestor within the last million years (Meyer, A., 1993; Turner, G. F. *et al.*, 2001). Their rapid evolution is thought to be the result of sexual selection and the evolution of mate choice. Most species are sexually dimorphic and visual communication is crucial for mate choice (for reviews see Seehausen, O., 2000; Kocher, T. D., 2004).

Typically, adult African cichlids possess three cone visual pigments, with nonidentical double cones maximally sensitive at longer wavelengths and shorter-wavelength-sensitive single cones (Fernald, R. D. and Liebman, P. A., 1980; Van der Meer, H. J. and Bowmaker, J. K., 1995; Carleton, K. L. *et al.*, 2000; Carleton, K. L. and Kocher, T. D., 2001; Parry, J. W. L. *et al.*, 2005; Jordan, R. *et al.*, 2006). Measurements of cone spectral sensitivities by MSP from a relatively small sample of species from Lake Malawi suggest that cichlids inhabiting rock and sand habitats have significantly different cone visual sensitivities (Carleton, K. L. and Kocher, T. D., 2001). The Mbuna (rock-dwelling) species tend to have double cones with maximum sensitivities at about 535 and 488 nm and ultraviolet- or violet-sensitive single cones with λ_{max} at about 370 or 420 nm. In contrast, non-Mbuna species that are more sand-dwelling may be less sensitive to short wavelengths, possessing double cones with maximum sensitivities at about 570 and 535 nm and blue-sensitive single cones with λ_{max} at about 450 nm (Levine, J. S. and MacNichol, E. F., 1979; Carleton, K. L. *et al.*, 2000; Parry, J. W. L. *et al.*, 2005; Jordan, R. *et al.*, 2006). However, in some species, notably *Pseudotropheus acei* (an Mbuna species), rare additional cones have been identified suggesting that at least seven spectrally distinct cone pigments may be expressed in the retina (Figure 3 and Table 1) (Parry, J. W. L. *et al.*, 2005).

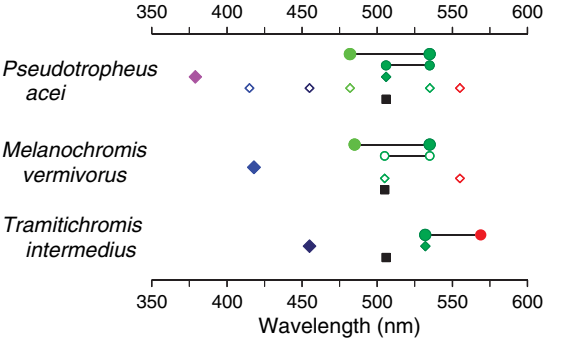

Figure 3 Distribution of the different cone types in three species of cichlids from Lake Malawi. Filled circles: double cones; size reflects relative frequency. Open circles: rare or individual double cones. Filled diamonds: single cones; size reflects relative frequency. Open diamonds: rare or individual single cones. Filled squares: rods. The color code reflects the four cone opsin gene classes: red, LWS; green, Rh2; blue, SWS2, and violet, SWS1. Data from Parry J. W. L., Carleton, K. L., Spady, T., Carboo, A., Hunt, D. M., Bowmaker, J. K. 2005. Mix and match color vision: tuning spectral sensitivity by differential opsin gene expression in Lake Malawi cichlids. Curr. Biol. 15, 1734–1739.

[c]Carleton K. L. and Kocher T. D. (2001).
[d]Matsumoto Y. *et al.* (2006).
[e]Fuller R. C. *et al.* (2004; 2003).
The expressed cone pigment data are from gene sequences amplified from retinal cDNA, expressed in mammalian cells, and regenerated with 11-*cis*-retinal *in vitro* (Parry, J. W. L. *et al.*, 2005; Spady, T. C. *et al.*, 2006).

Analysis of the opsin gene complement from two species, *Metriaclima zebra* (Mbuna) and the Nile tilapia (*Oreochromis niloticus*) (Parry, J. W. L. *et al.*, 2005), has demonstrated that of the seven genes, three are from the Rh2 gene class, two from the SWS2 class, with single representatives of the LWS and SWS1 gene classes. The Nile tilapia is considered to be the riverine equivalent of the ancestors of the lake cichlids. In order to correlate opsin gene sequences with the different pigments identified by MSP, all seven gene sequences have been amplified from retinal cDNA, expressed in mammalian cells, and regenerated with 11-*cis*-retinal *in vitro* (Parry, J. W. L. *et al.*, 2005; Spady, T. C., *et al.*, 2006).

The data demonstrate that gene duplication in the green-sensitive Rh2 gene of cichlids has occurred on at least two occasions (Figure 4). There was a relatively ancient duplication, leading to Rh2A and Rh2B genes, which occurred after the divergence of the Acanthopterygii from other teleosts, sometime between 260 MYA (Kumazawa, Y. *et al.*, 1999) and 115–200 MYA (Furutani-Seiki, M. and Wittbrodt, J., 2004). The two genes have diverged such that their expressed cone pigments may be separated by as much as 50 nm. The Rh2A pigments have λ_{max} as long as about 535 nm, whereas the Rh2B pigments absorb maximally at shorter wavelengths around 480 nm. The second, much more recent duplication of the Rh2A gene probably occurred within the past 10 MYA only in the intralacustrine cichlid radiation (Kocher, T. D. *et al.*, 1995). The duplication has led to two spectrally distinct classes, Rh2Aα and Rh2Aβ, with λ_{max} around 525–535 nm and 505–520 nm, respectively (Parry, J. W. L. *et al.*, 2005; Spady, T. C., *et al.*, 2006).

Since adult cichlids express predominantly only three of the seven available opsins, the question arises as to what function maintains the presence of the other genes. Genes that are not expressed would be expected to evolve free of any constraints of selective pressure and would build up random mutations leading to nonfunctionality. The functional opsins may be differentially expressed spatially and/or temporally. Regional variations of cone pigments across the retina and ontogenetic changes in cone opsin expression are not uncommon both in teleosts and mammals. Variations in expression across the retina have not been described in these cichlids, but ontogenetic changes have been established, at least in tilapia. Using quantitative methods to determine levels of gene expression, Spady T. C. *et al.* (2006) have shown that larval tilapia primarily express four of the seven opsins – SWS1, Rh2B, Rh2Aα, and LWS – at approximately equal levels (Figure 5). However during development there is a major switch in expression with a marked downregulation of the SWS1 and Rh2B genes and a significant upregulation of the SWS2A and LWS gene. Adult tilapia primarily express only three opsins: SWS2A, Rh2Aα, and LWS, with the LWS noticeably dominant.

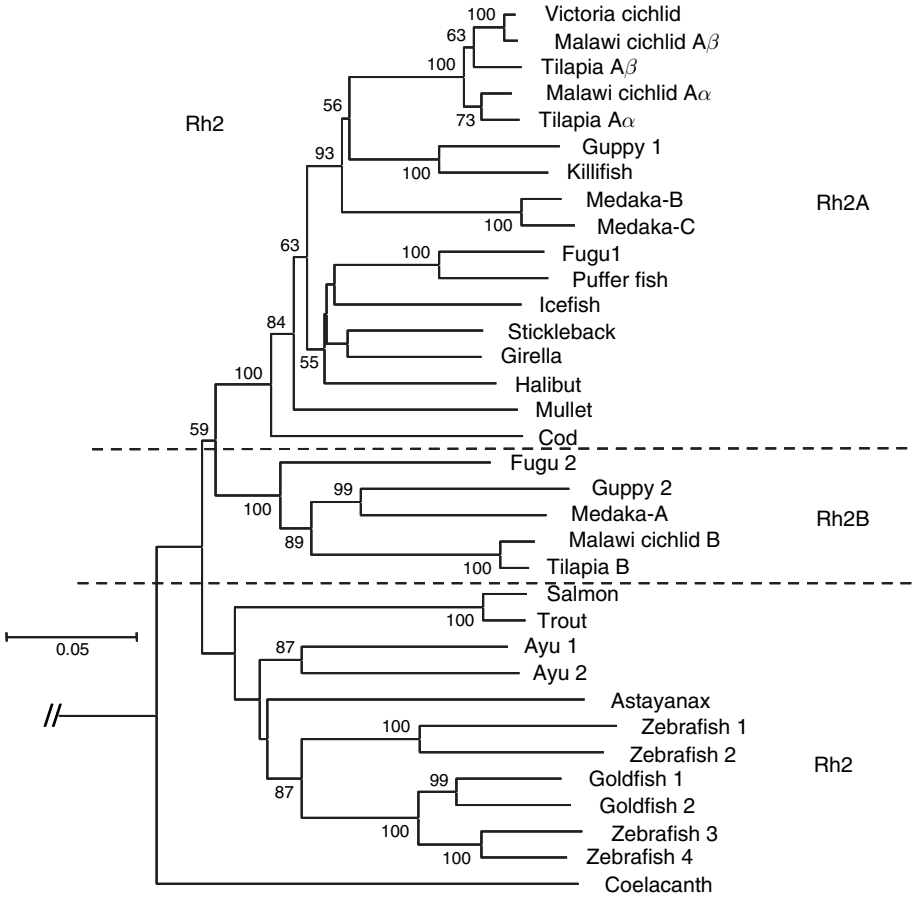

Figure 4 Phylogeny of teleost's Rh2 cone opsin genes. Nucleotide sequences were aligned by ClustalW, and the tree was generated by the neighbor-joining method (Saitou, N. and Nei, M., 1987). The bootstrap confidence values (1000 replicates) are shown for each branch. The *Drosophila* Rh4 sequence (M17719) was used as an outgroup (not shown). The scale bar is equal to 0.05 substitutions per site. The dashed lines indicate the divergences of the three classes of Rh2 gene. Sequences were obtained from Genbank accession numbers AY673755, DQ088650, DQ235682, DQ088651, DQ235683, DQ234859, AY269739, AB223054, AB223055, AF226989, AY598944, AY771354, BT027598, AB158259, AF156263, Y18680, AF385824, AY599603, DQ234858, AB223053, DQ088652, DQ235681, AY214132, AF425076, AB098703, AB098704, AH004622, AB087805, AB087806, L11865, L11866, AB087807, AB087808, AF131258.

From this it can be inferred that larval tilapia are potentially tetrachromatic with sensitivity extending into the near ultraviolet, but that adults are limited to trichromacy and are primarily long-wave-sensitive. This supposition is supported by MSP data (Loew, personnel communication) where larval fish have been shown to possess at least four spectral cone classes, including UV-sensitive small single cones, whereas adults possess only three spectral cone classes, double cones that are either red/red or red/green and blue-sensitive single cones. The presence of red/red and red/green double cones reflects the predominant expression of the LWS gene in the adult fish. (Ontological variation in cone pigments is discussed more fully below.)

Phylogenetic analysis indicates that the duplication into Rh2A and Rh2B occurred early in the radiation of teleosts, at least before the divergence of the Paracanthopterygii (including gadids) and the Acanthopterygii (including cichlids) (Figure 4), which is thought to have occurred somewhere between 260 MYA (Kumazawa, Y. *et al.*, 1999) and 115–200 MYA (Furutani-Seiki, M. and Wittbrodt, J., 2004). Thus all of the orders within the percomorph teleosts should show evidence of the Rh2A and Rh2B genes, and these have been identified in the guppy (*Poecilia reticulata*, Atherinomorpha,

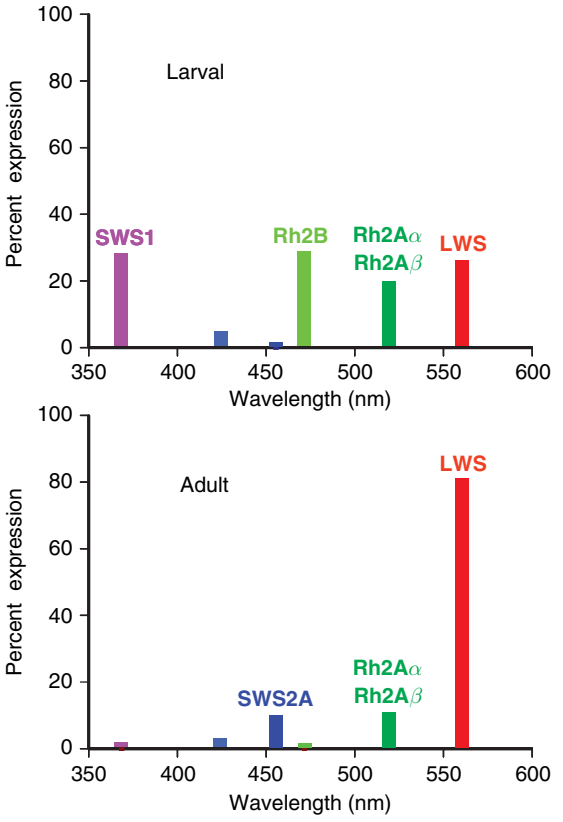

Figure 5 Relative cone opsin expression profiles for larval and adult tilapia, *Oreochromis niloticus*. At larval stages, four of the seven cone opsin genes are predominately expressed giving the potential for tetrachromatic color vision. In the adult there is a marked downregulation of the SWS1 gene with a greatly enhanced expression of the LWS gene. Adult tilapia are potentially trichromatic. Data from Spady T. C., Parry, J. W. L., Robinson, P. R., Hunt, D. M., Bowmaker, J. K., and Carleton, K. L. 2006. Evolution of the cichlid visual palette through ontogenetic subfunctionalization of the opsin gene arrays. Mol. Biol. Evol. 23, 1–10.

Cyprinodonti-formes) (Hoffmann, M. *et al.*, 2006) and medaka (*Oryzias latipes*, Atherinomorpha, Beloniformes) (Matsumoto, Y. *et al.*, 2006), which has a pattern of cone opsin genes very similar to the African cichlids. In medaka, the orthologous gene to the cichlid Rh2B gene has been confusingly designated Rh2A with λ_{max} at 452 nm, and, as in the cichlids, the orthologous gene to the Rh2A is duplicated, the two genes termed Rh2B and Rh2C with λ_{max} at 516 and 492 nm, respectively (Table 1). It is notable that the three Rh2 pigments in medaka are substantially displaced to shorter wavelengths than the cichlids (as are the two SWS2 pigments). The phylogeny of these Rh2 genes implies that the second duplication in medaka and the cichlids is independent (Figure 4). However, it is possible that the duplications have a common origin and subsequent gene conversion has removed any trace of long divergence (Matsumoto, Y. *et al.*, 2006).

In the guppy, although there are data for both the cone visual pigments from MSP (Archer, S. N. *et al.*, 1987; Archer, S. N. and Lythgoe, J. N., 1990) and the opsin genes (Hoffmann, M. *et al.*, 2006), it is not straightforward to match the two sets of data. MSP identified shorter-wave-sensitive pigments with λ_{max} around 360, 408, and 464 nm and an apparent polymorphism of cone pigments in the red/green spectral region with cones having λ_{max} at about 533, 548, and 572 nm. Differences were found between individual fish in the occurrence of these three longer-wave pigments. Hoffmann M. *et al.* (2006) suggest that the variations in the longer-wave pigments is a result of gene duplication and polymorphism of the guppy's LWS gene (see below) and that the Rh2A and Rh2B cone pigments have similar absorbance or are differentially expressed during development. However, given the data from cichlids and medaka, it is as likely that the 464 and 533 nm pigments are expression of the Rh2B and Rh2A genes, respectively.

The orthologous gene to the Rh2A cichlid gene has been identified in a number of other percomorphs, but in many instances the Rh2B orthologue has not been identified or has been reduced to a pseudogene. It is not clear whether this is because the gene has been lost or simply missed in the analysis of opsin genes. Within the Tetraodontiformes, the fugu (*Takifugu rubripes*) and the puffer fish (*Tetraodon nigroviridis*) possess a functional orthologue of the cichlid Rh2A gene (Figure 4), but the orthologue of the Rh2B has apparently been truncated to a pseudogene relatively recently (Neafsey, D. E. and Hartl, D. L., 2005). In five species of Antarctic notothenioid ice fish (Pointer, M. A. *et al.*, 2005), MSP has identified only a single spectral class of green-sensitive cone with λ_{max} close to 490 nm. Only a single Rh2 gene was isolated from one of the species (*Dissostichus mawsoni*) and *in vitro* expression and regeneration of the gene gave a similar peak absorbance to that obtained by MSP. These data together suggest that at least in this suborder of percomorphs, the duplicate Rh2B gene may have been lost.

A further group of percomorphs in which both MSP and molecular genetics of cone opsins are available are the killifish (Atherinomorpha, Cyprinodontiformes). In the bluefin killifish (*Lucania goodei*) five cone pigments have been identified by MSP and five cone opsins isolated (Table 1) (Fuller, R. C. *et al.*, 2003; 2004). This species apparently has only a single Rh2 gene that is orthologous to the cichlid Rh2A and is expressed as a green-sensitive 537 nm pigment. Again, as in the ice fish, has this species lost the Rh2B variety or has it simply been missed? In the closely related killifish, *Fundulus heteroclitus*, only four spectral classes of cone have been identified by MSP (Novales Flamarique, I. and Hárosi, F. I., 2000). The two short-wave pigments with λ_{max} at 363 and 400 nm are presumably expressed from SWS1 and SWS2B genes and the long-wave 563 nm pigment from an LWS gene. However, the middle-wave pigment with λ_{max} at 463 nm could be the expression of either an SWS2A or an Rh2B gene. If it is the SWS2A gene, then these data would suggest that there is no expression of any of the Rh2 genes in this species.

Gene duplication of the Rh2 gene has also occurred independently within the cyprinids (Figure 4). Goldfish express two Rh2 genes that yield cone pigments spectrally separated by only about 6 nm when reconstituted with 11-*cis* retinal (505 and 511 nm) (Johnson, R. L. *et al.*, 1993). Zebrafish have a double duplication leading to four spectrally distinct Rh2 genes arranged in a tandem array, with expressed pigments, again based on 11-*cis* retinal, with λ_{max} ranging from 467 to 505 nm (Chinen, A. *et al.*, 2003; 2005a). In zebrafish there are clear changes in the temporal and spatial pattern of expression of the four pigments in the embryo during the first few days post fertilization (Takechi, M. and Kawamura, S., 2005), but the functional significance of this is difficult to determine. It is most likely that the opsins are coexpressed at various stages during development. In adult goldfish, we have been unable to show that the two Rh2 opsins are expressed in separate classes of cone with the λ_{max} of the green half of double cones and the long single green cones being identical (unpublished observations). This is in contrast to the ayu (an osmerid salmonid) where its two Rh2 genes are expressed separately in one half of the double cones and in long single cones (Minamoto, T. and Shimizu, I., 2005), though their λ_{max} have not been determined.

1.04.8.3 SWS2 (Short-Wave Blue/Violet-Sensitive) Opsin Duplication

Phylogenetic analysis shows that the SWS2 gene duplicated in the early ancestry of the Acanthopterygii in a similar fashion as the Rh2 gene (Figure 6). Mutations have led to two spectrally distinct subfamilies, the SWS2A having λ_{max} around 440–455 nm and SWS2B with λ_{max} at shorter wavelengths between about 405 and 425 nm. These opsin genes and their expressed pigments have been identified in cichlids (Carleton, K. L. and Kocher, T. D., 2001; Parry, J. W. L. *et al.*, 2005; Spady, T. C. *et al.*, 2006), medaka (Matsumoto, Y. *et al.*, 2006), and the killifish (Fuller, R. C. *et al.*, 2003; 2004). In medaka and killifish, the SWS2B pigments have λ_{max} at 405 nm and in cichlids around 415–425 nm. A duplication of the SWS2 gene has not been reported in teleosts outside of the Acanthopterygii, though the two blue-sensitive pigments of the longnose gar (441 and 427 nm) may be another example. If both these two pigments prove to be an expression of SWS2 genes, then it is likely that this duplication in the Holostei occurred independently of the duplication in the Acanthopterygii.

In teleosts other than Acanthopterygii, although SWS2 gene duplication is not apparent, a similar dichotomy in the spectral location of SWS2 pigments appears to have occurred in cyprinids. In goldfish the SWS2 pigment reconstituted with 11-*cis* retinal has λ_{max} at 441–443 nm (Johnson, R. L. *et al.*, 1993; Chinen, A. *et al.*, 2005b) (453 nm as a porphyropsin (Hárosi, F. I. and MacNichol, Y., 1974; Bowmaker, J. K. *et al.*, 1991) similar to the λ_{max} of the blue-sensitive cone pigments of carp (Hárosi, F. I., 1985), roach, *Rutilus rutilus* (Avery, J. A. *et al.*, 1983; Downing, J. E. G. *et al.*, 1986), and tench, *Tinca tinca* (Loew, E. R. and Lythgoe, J. N., 1978). In contrast, zebrafish SWS2 pigment has λ_{max} at 407–416 nm (Nawrocki, L. *et al.*, 1985; Robinson, J. *et al.*, 1995; Palacios, A. G. *et al.*, 1996; Cameron, D. A., 2002; Chinen, A. *et al.*, 2003) and the Japanese dace, *Tribolodon hakonensis* (Hárosi, F. I. and Hashimoto, Y.,1983), and rudd, *Scardinius erythrophthalmus* (Whitmore, A. V. and Bowmaker, J. K., 1989), similarly have a blue-sensitive cone pigment with λ_{max} around 405–415 nm. (Rudd have also been reported to have a blue-sensitive cone with λ_{max} at 450–460 nm (Loew, E. R. and Dartnall, H. J. A., 1976).) Chinen A. *et al.* (2005) have reconstructed the likely ancestral SWS pigment of the goldfish and zebrafish, which, when expressed with 11-*cis* retinal, has a maximum absorbance at 430 nm, indicating that mutations

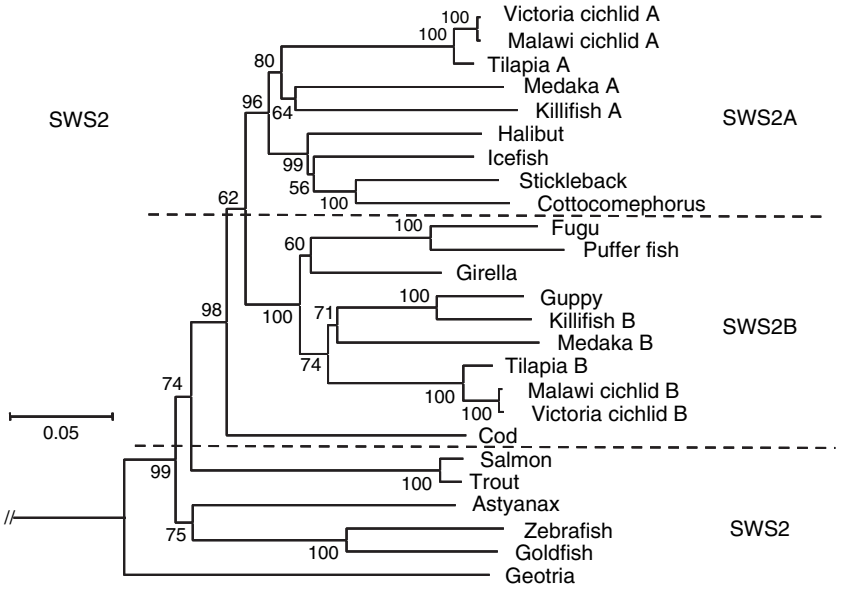

Figure 6 Phylogeny of teleost's SWS2 cone opsin genes. Nucleotide sequences were aligned by ClustalW, and the tree was generated by the neighbor-joining method (Saitou, N. and Nei, M., 1987). The bootstrap confidence values (1000 replicates) are shown for each branch. The *Drosophila* Rh4 sequence (M17719) was used as an outgroup (not shown). The scale bar is equal to 0.05 substitutions per site. The dashed lines indicate the divergences of the three classes of SWS2 gene. Sequences were obtained from Genbank accession numbers AY673763, AF247114, AF247116, AB223056, AY296737, AF316497, AY771356, BT027452, AJ430479, AY598947, AY598948, AB158256, DQ234860, AY296736, AB223057, AF247120, AF317674, AY673708, AF385822, AY214134, AF425075, AF134762, AF109372, L11864, AY366492.

have occurred in both species to displace the pigment to longer and shorter wavelengths, respectively.

Although data are somewhat limited, it is noticeable that both in some groups of the Acanthopterygii and in the cyprinids, teleost groups that diverged over 100 MYA, the blue-sensitive cone pigments, appear to fall into two spectral groups centered around 410–420 and 440–450 nm. Is this a limitation of the data or are these locations driven by ecological factors or determined by structural constraints on opsins? Outside of teleosts, the short-wave-sensitive cone pigments of birds also fall into these two spectral locations. All avian species studied to date have a blue-sensitive pigment (SWS2) with λ_{max} close to 450 nm, and birds that lack a true UV-sensitive cone possess a violet-sensitive pigment with λ_{max} at about 405–420 nm (Okano, T. *et al.*, 1992; Bowmaker, J. K. *et al.*, 1997; Hart, N. S., 2001). In the avian retina, the violet-sensitive pigments are the expression of an SWS1 opsin and are not the product of the SWS2 opsin. Indeed, this would appear to be the case in all vertebrate groups with the exception of teleosts. In mammals, including humans, where the S-cone pigment has λ_{max} at about 420 nm (Dartnall, H. J. A. *et al.*, 1983; Oprian, D. D. *et al.*, 1991; Merbs, S. L. and Nathans, J., 1992; Fasick, J. I. *et al.*, 1999), all the short-wave-sensitive pigments are SWS1 pigments and the SWS2 gene has been completely lost.

1.04.8.4 SWS1 (Short-Wave Violet/Ultraviolet-Sensitive) Opsin Duplication

Duplication of SWS1 genes appears to be rare within teleosts and all the reported SWS1 pigments are expressed as true UV-sensitive pigments with λ_{max} between 350 and 380 nm (Parry, J. W. L. and Bowmaker, J. K., 2000; Cowing, J. A. *et al.*, 2002; Chinen, A. *et al.*, 2003; Parry, J. W. L. *et al.*, 2005; Matsumoto, Y. *et al.*, 2006; Spady, T. C. *et al.*, 2006). The exception to this is the smelt, ayu (*P. altivelis*), where two SWS1 genes have been identified (Minamoto, T. and Shimizu, I., 2005), but one of the pair (SWS1-1) is expressed at a very low level and could not be identified by *in situ* hybridization (Figure 7). The spectral sensitivity of the two opsins is not known and it may be that they are spectrally identical. It would appear that the tuning mechanisms that have evolved in other vertebrate groups to

tune SWS1 opsins to longer wavelengths above 400 nm (Yokoyama, S. *et al.*, 2000; Shi, Y. S. *et al.*, 2001; Cowing, J. A. *et al.*, 2002; Shi, Y. S. and Yokoyama, S., 2003; Hunt, D. M. *et al.*, 2004; Parry, J. W. L. *et al.*, 2004; Wilkie, 2000 #5625) have not been achieved in teleosts, where violet sensitivity is achieved through SWS2B opsins.

1.04.8.5 LWS (Long- to Middle-Wave Red/Green-Sensitive) Opsin Duplication

Duplication of the LWS gene appears to have occurred independently in a number of groups (Figure 7). Within the Acanthopterygii, duplication has been identified in girella (Perciformes) (Miyazaki, T. *et al.*, 2005) and the Atherinomorphs, medaka (Beloniformes) (Matsumoto, Y. *et al.*, 2006), killifish (Cyprinodontiformes) (Blow and Yokoyama, Genbank accession numbers AY296735–AY296741), and guppy (Cyprinodontiformes) (Hoffmann, M. *et al.*, 2006). These duplications appear to have occurred independently, but it is possible that they have a common origin, at least within the Atherinomorphs, and subsequent gene conversion has removed any trace of long divergence. Outside of the Acanthopterygii, LWS gene duplication also occurs in zebrafish (Cypriniformes) (Chinen, A. *et al.*, 2003) and the cave fish *Astyanax* (Characiformes) (Yokoyama, R. and Yokoyama, S., 1990).

In *Astyanax* three LWS genes have been identified, and based on the known tuning sites between primate L- and M-cones, it is clear that one of the genes (r007, LR in Figure 7) corresponds to a red-sensitive pigment with λ_{max} at about 565 nm and that the other two similar genes (g101 and g103, LG1 and LG3 in Figure 7) correspond to a green-sensitive pigment with λ_{max} at about 535 nm (Yokoyama, R. and Yokoyama, S., 1990; Kleinschmidt, J. and Hárosi, F. I., 1992; Yokoyama, S. and Radlwimmer, F. B., 2001; Parry, J. W. L. *et al.*, 2003). This is a striking illustration of convergent evolution, where exactly the same amino acid substitutions are found tuning between the 535 and 565 nm cone pigments in both primates and *Astyanax*. Another characid, a tetra, *Paracheirodon innesi* is reported similarly to have the two g-variations of the LWS gene (Kasai and Oshima, Genbank accession numbers AB239249 and AB239250). Somewhat surprisingly, phylogenetic analysis implies that the divergence of the red and green versions of the LWS gene occurred at the base of the teleosts, before the separation of the characids and cyprinids from the Acanthopterygii, but homologous genes to the green genes of the characids have not been identified in any other teleost groups.

In zebrafish the two LWS genes have been expressed with λ_{max} at 558 and 548 nm (Chinen, A. *et al.*, 2003), but there is no evidence from MSP for two spectrally distinct populations of LWS cones, though different groups report slightly different λ_{max} ranging from 556 to 570 nm (Nawrocki, L. *et al.*, 1985; Robinson, R. *et al.*, 1993; Cameron, D. A., 2002). Also, two LWS genes have been identified in killifish, but their spectral sensitivities have not been published and again there is no evidence of two populations of LWS cones in the retina (Fuller, R. C. *et al.*, 2004). In both zebrafish and killifish, the lack of evidence for two populations of LWS cones may simply be that the rather limited MSP data are insufficient to distinguish two pigments separated perhaps by only a few nanometers or that the two pigments are coexpressed. In medaka the duplicated genes have similar spectral sensitivities (Matsumoto, Y. *et al.*, 2006). In the guppy, at least two LWS genes are present (Hoffmann, M. *et al.*, 2006) and MSP of cones gives three potential λ_{max} at about 533, 548, and 572 nm (Archer, S. N. and Lythgoe, J. N., 1990). As suggested above, the 533 nm pigment may represent an Rh2A gene, leaving the two longer cone pigments as candidates for LWS genes. However, Archer S. N. and Lythgoe J. N. (1990) suggested that the 548 nm cones might be coexpressing the 533 and 572 nm pigments. The precise arrangement of pigments will only be resolved with further work on the expression of the isolated opsin genes.

Duplication of the LWS gene would seem to be the most likely explanation for the observation from MSP that at least in three species of pike, *Esox niger*, *Esox lucius*, and *Esox masquinongy* (Esocidae), the two halves of the long-wave-sensitive double cones (nonidentical twins) contain LWS pigments spectrally separated by about 15 nm, with λ_{max} at about 616 and 630 nm (Loew, E. R. *et al.*, 2006). These pigments are porphyropsins and there is no evidence that the spectral difference is a result of a small inclusion of a rhodopsin in the shorter half of the twin cone. The Esocidae are highly divergent both from the cyrinids and from the Acanthopterygii and the presumed LWS gene duplication in pike must be independent of the duplications within the other groups.

1.04.8.6 Ontogenetic Changes in Visual Pigment Complement

To the extent that visual pigments set the boundary for visual perception of both intensity and color, it should not be surprising that as the visual tasks and environment of a fish change during their development, so should their visual capabilities. This idea was initially supported by extraction studies on rods, showing chromophore shifts between rhodopsins and porphyropsins, and therefore peak absorbance shifts that are associated with changing environmental parameters such as the spectrum of the background spacelight, day length, temperature (e.g., see reviews of Bridges, C. D. B., 1972 and Bowmaker, J. K., 1995). That cones could also exchange chromophores was confirmed later using MSP (for a review, see Bowmaker, J. K., 1995). Almost all of the early work was carried out on mature fish or salmonids at the parr-to-smolt transition. However, a rich literature has developed directed specifically at larval-to-juvenile-to-adult transitions, from the points of view of chromophore shifting, opsin expression, and cellular changes. This is facilitated by the ability to determine opsin genotype and phenotype at the molecular level while also being able to determine expression patterns in time and space. To the visual ecologist interested in adaptive significance, these capabilities, when applied to temporal metamorphoses, are of particular use, since the visual world and tasks of most larvae are simple compared to those of adults, making modeling far easier (see below).

1.04.8.7 Simple Opsin Expression/Cellular Trajectories

The term simple is used here to describe trajectories not involving opsin switching in differentiated cones, as described for cichlids and others in this chapter. A good example of how available techniques can be applied to this kind of system can be found in the winter flounder, *Pleuronectes americanus* (Percomorpha). Early studies used histology and MSP to follow the retinal and visual pigment changes taking place during premetamorphic and postmetamorphic periods (Evans, B. I. and Fernald, R. D., 1993; Evans, B. I. *et al.*, 1993; see also Evans, B. I., 2004). Opsin expression studies using reverse transcriptase polymerase chain reaction (RT-PCR) on pre- and postmetamorphic stages have been added to this (Mader, M. M. and Cameron, D. A., 2004). The first cells to appear during ontogeny in premetamorphic fish are single cones with λ_{max} at about 520 nm expressing a single Rh2 opsin gene. With development are added rods at 509 nm expressing an Rh1, single cones at 461 nm expressing an SWS2, and double cones with 529 and 547 nm pigments expressing Rh2 and LWS opsin, respectively. No evidence of a UV pigment was found at any stage, although the presence of an SWS1 gene cannot be excluded. Interestingly, the authors suggest that a single Rh2 opsin produces both the 520 nm pigment in the premetamorphic fish and the 529 nm pigment in one member of the postmetamorphic double cone. They base this on their inability to identify more than one Rh2 product using RT-PCR and cross-reactivity of *in situ* probes. However, since flounders are percomorphs (and closely related to halibut, see Figure 4), they have the potential of possessing both an Rh2A and an Rh2B opsin gene and it may be that a second Rh2 gene is present, but has yet to be isolated.

The finding that cones precede rods during ontogeny appears to be the rule, although the first pigment(s) to be expressed may vary. An Rh2 opsin appears first in winter flounder as well as in the sturgeon and catfish (based on λ_{max} position determined by MSP (Sillman, A. J. *et al.*, 1993; Sillman, A. J. and Dahlin, D. A., 2004)). This is followed by rods and other single-cone classes that can express any of the other opsin gene classes. Last to develop are paired cones, either twin or double. For other species, such as goldfish (Stenkamp, D. L. *et al.*, 1996; 1997) and zebrafish (Raymond, P. A. *et al.*, 1993; 1995), the order appears to be LWS, Rh2, SWS2, and SWS1, although more recent evidence suggests that the blue opsin is expressed first in zebrafish (Takechi, M. and Kawamura, S., 2005).

1.04.8.8 Complex Opsin Expression/Cellular Trajectories

Not all species show the successive addition of photoreceptor classes, each expressing a single opsin type, as described for the winter flounder. Rather, there can be expression shifts within already present photoreceptors, as well as cone additions and apoptotic losses. For many years the only examples of an opsin change in a preexisting photoreceptor producing an ontogenetic λ_{max} shift were the eels, *Anguilla rostrata* and *Anguilla anguilla* (Beatty, D. D., 1975; Wood, P. and Partridge, J. C., 1993), and the cardinal fish, *Apogon brachyrammus* (Munz, F. W. and McFarland, W. N., 1975). From the above discussion,

it is obvious that changes in opsin expression, with or without the loss or gain of new cone types, are quite common in both marine and freshwater fishes. The most frequently observed alterations are in the expression of short-wavelength opsins and the presence of UV cones. The only published reports of changes involving long-wavelength opsin expression are for the goatfish, *Upeneus tragula* (Percomorpha) (Shand, J., 1993) and yellowfin tuna, *Thunnus albacares* (Percomorpha) (Loew, E. R. *et al.*, 2002). Examples of the kinds of shifts in both opsin expression and retinal structure are given below.

1.04.8.9 Short-Wavelength Shifts: Salmonids and the Lingcod

More is known about the developmental and life history changes in retinal architecture and visual pigment complement in salmonids than for any other group. Early literature concentrated on rhodopsin/porphyropsin shifts in rods (see Bridges, C. D. B., 1972) and later the cones (see, e.g., Bowmaker, J. K. and Kunz, Y. W., 1987; Hawryshyn, C. W. and Hárosi, F. I., 1994; Cheng, C. L. *et al.*, 2006). Most of the changes involve the loss and gain of UV photoreceptors and their correlation with life history events. Whereas there remains some controversy about the timing and pattern of loss, it appears that UV cones can follow two paths during development. In the Pacific salmonids studied by Cheng C. L. *et al.* (2006) only single cones are present at hatching and all express an SWS1 opsin. Downregulation of UV opsin expression later in development is associated either with the loss of the UV cell through apoptosis (this is associated with the well-documented loss of small corner cones as seen at the parr-to-smolt transition) or with the increased expression of a blue opsin gene leading to a shift in spectral sensitivity. The latter process was confirmed both by MSP and by *in situ* labeling (Cheng, C. L. and Novales Flamarique, I., 2004). The pattern is somewhat different for the Atlantic salmon, but changes in overall spectral sensitivity at the short-wavelength end of the spectrum seem to be a common feature among salmonids.

The lingcod, *Ophiodon elongatus* (Percomorpha), also shows changes in SWS1 and SWS2 opsin expression (see Table 2 containing unpublished data used with the permission of Lyle Britt). The larvae are near-surface diurnal planktivores, whereas adults can be found from the surface to depths in excess of 400 m (Allen, M. J. and Smith, G. B., 1988). At the time of hatching, only the UV cones are present, although they are few and disappear very quickly. At preflexion there is definite expression of UV-, violet-, green-, and red-sensitive cones (all single cones), presumably expressing SWS1, SWS2(B), Rh2, and LWS opsin genes, respectively. Between preflexion and flexion, there is a rapid loss of UV cones, presumably due to downregulation of the SWS1 gene and most likely apoptosis of the UV cells.

At the time of prejuvenile-to-juvenile transformation, all of the violet-sensitive cones show a spectral shift toward the blue, which can be interpreted as

Table 2 Visual pigments (λ_{max} in nm ± SD) versus developmental stage for the lingcod

Photoreceptor	*Preflexion*	*Flexion*	*Postflexion*	*Prejuvenile*	*Transformation*	*Juvenile*	*Adult*
Rod		500 ± 1	500 ± 1	499 ± 2	501 ± 3	500 ± 2	499 ± 2
Single cones							
UV	364 ± 9						
Violet	405 ± 4	402 ± 2	402 ± 1	407 ± 6			
Violet/blue					421 ± 19		
Blue						460 ± 5	461 ± 1
Green	514 ± 1	512 ± 1	512 ± 2	513 ± 2	517 ± 2	521 ± 1	523 ± 1
Yellow	564 ± 6	564 ± 2	565 ± 1	568 ± 3	565 ± 5		
Double cones							
Green member					519 ± 2	522 ± 1	522 ± 4
Yellow member					567 ± 4	565 ± 4	563 ± 7
Twin cones					519 ± 3	520 ± 2	521 ± 3

Note that the rods do not appear until the flexion stage, which is similar to that reported for a number of other species (e.g., tuna (see below) and salmonids (see above)). The same is true for a number of other Pacific Northwest marine species. However, in several species rods were present at the preflexion stage along with single cones (Britt, L. L. *et al.*, 2001).
From Britt, L. L., 2006.

a change in opsin gene expression and coexpression from the SWS2 opsin gene to either a second SWS2(A) opsin gene or an Rh2 opsin. By the end of this transformation, which takes only about 48 h, all of the violet-sensitive cones have become blue-sensitive. There is also an apparent small long-wave shift in the green-sensitive single cones from about 512 to 522 nm. This may well reflect a switch between two Rh2 opsin genes. The final adult complement consists of the expression of the LWS, an Rh2, and probably the SWS2A opsin genes. These MSP data suggest the ontological expression of at least six cone opsin genes, somewhat similar to that described earlier for cichlids. Lingcod, more closely related to the cottoids, is, like the cichlids, a percomorph, where gene duplication of both Rh2 and SWS2 opsin genes has occurred (see Figures 4 and 6). In salmonids, there is no evidence of transformation or coexpression in the green Rh2 or red LWS cones. The adaptive significance of the two sequential changes in short-wavelength sensitivity remains obscure.

1.04.8.10 Long-Wavelength Shifts: Yellowfin Tuna

The retinas of postflexion through adult tuna are highly developed, containing rods and single and twin cones (Margulies, D., 1997). The adult eye is large and together with a high cone density endows tuna and billfish with the highest visual acuity reported in fishes (Tamura, T. and Wisby, W. J., 1963; Nakamura, E. L., 1968; 1969). The single cones contain a visual pigment with λ_{max} at 426 nm and the identical twin cones and rods contain pigments with λ_{max} around 485 nm (Loew, E. R. *et al.*, 2002). Preliminary analysis of the opsin genes has identified single LWS and SWS2 genes and at least two Rh2 genes (Carleton, K. R., personnel communication). The SWS2 gene and an Rh2 gene presumably correlate with the 426 and 485 nm adult cone pigments, respectively. However, no LWS cones have been seen in adult yellowfin tuna in spite of extensive searching (note that LWS cones have been reported in marlin (Fritsches, K. A. *et al.*, 2003)), but an LWS visual pigment has been identified by MSP in larval yellow perch (Loew, E. R. *et al.*, 2002).

In yellowfin tuna, the retinal anatomy of first feeding through flexion larvae is quite different from the adult (see Margulies, D., 1997). Only single cones are found in first feeders, with rods not becoming evident until late flexion/early postflexion. Small twin cones appear during postflexion and greatly increase in size through the juvenile stages. Associated with these retinal and developmental changes are changes in prey type. A summary of visual pigment findings for yellowfin tuna cones at different developmental stages is presented in Figure 8 (Loew, E. R. *et al.*, 2002). The visual pigment complement for subadults is complex. At flexion (6–9 mm standard length, SL), when there are no observable rods and only single cones present, there is a broad range of λ_{max} essentially spanning the wavelength range from 418 to 575 nm. With increasing SL there is a decrease in overall range of single cone λ_{max} with some suggestion of clustering around the 426 nm single-cone adult value, and an absence of values in the 430 to 480 nm range. A second convergence leads to a single-cone cluster around 485 nm at 43 mm SL. Twin cones are first evident at the early juvenile 1 stage (21 mm SL). Here too, there is λ_{max} heterogeneity that converges to the 485 nm adult value by the end of the juvenile 1 stage.

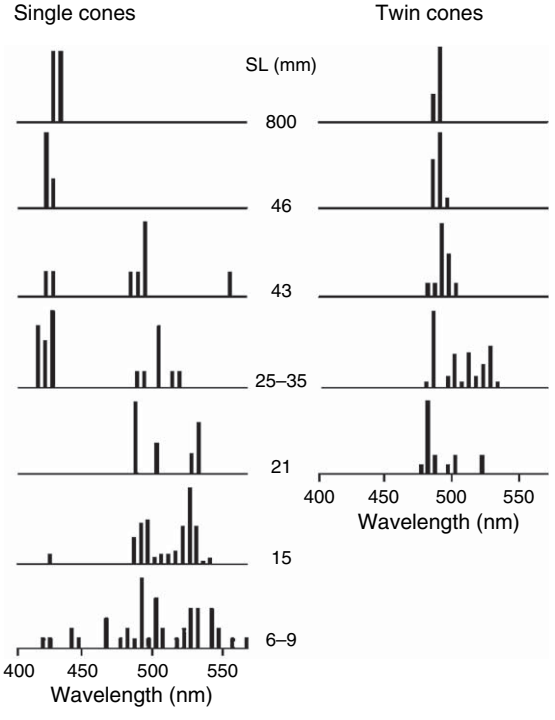

Figure 8 Cone visual pigments versus standard length (SL) for yellowfin tuna. Reproduced from Loew, E. R., McFarland, W. N., and Margulies, D. 2002. Developmental changes in the visual pigments of the yellowfin tuna, *Thunnus albacares*. Mar. Freshw. Behav. Physiol. 35, 235–246, with permission from Taylor & Francis.

Combining the MSP and molecular data, one can conclude that the SWS2 gene produces the 426 nm pigment, the Rh2 gene produces the 485 nm pigment, and the LWS gene produces a pigment with λ_{max} greater than 560 nm. The presence of measured pigments with λ_{max} substantially below 426 nm suggests the presence of an additional SWS1 gene that has yet to be identified. As with lingcod, tuna are percomorphs and so may have the possibility of at least six cone opsin genes.

1.04.9 Adaptive Significance

Knowledge of the overall spectral sensitivity of a fish at a particular life-history stage still needs to be rationalized in terms of its adaptive significance. This requires information on the visual tasks performed at that stage in a particular photic environment. As described above for cichlids (see also Carleton, K. L. *et al.*, 2006), this can be a very complex process, having to take into account differences in the turbidity and spectral characteristics of the water and the great variation in the size, shape, and spectral characteristics of relevant targets (e.g., conspecifics). Whereas some models have been developed, which try to take all these factors into account when deciding which complement of visual pigments is most efficient under a given set of conditions and tasks (see Loew, E. R. and Zhang, H., 2006; Marshall, J. *et al.*, 2006b), the degree of complexity in a group like the cichlids can be quite confounding. However, examination of relatively simple systems can lead to broad generalizations. The main visual task of larval fish is prey detection. For obligate diurnal planktivores this occurs in the top few meters of the water column in both marine and freshwater environments. Feeding usually takes place within a horizontal band over a few body lengths. Unless the fish is very close to an object, the background is basically featureless and described by the average horizontal radiance. For freshwater species the presence of a UV pigment in the larval/juvenile has been seen as an adaptation for planktivory (Bowmaker, J. K. and Kunz, Y. W., 1987; Browman, H. I. *et al.*, 1994; see reviews by Bowmaker, J. K., 1991; Beaudet, L. and Hawryshyn, C. W., 1999; Partridge, J. C. and Cummings, M. E., 1999). This is supported by the loss of UV cells with the transition to demersal piscivory (e.g., the perch, Loew, E. R. and Wahl, C. M., 1991), or a switch from UV to violet or blue opsin expression (e.g., salmonids, Cheng, C. L. *et al.*, 2006) and lingcod (Britt, L. L., personal communication). The cessation of LWS expression in yellowfin tuna and goatfish at the planktivory–piscivory transmission has already been mentioned, but this is not so easily explained since the optical characteristics of plankton contributing to contrast are not as spectacular at longer wavelengths (McFall-Ngai, M. J., 1990; Johnsen, S., 2001).

Recently, a unifying adaptive imperative, based on the above examples, as well as an extensive study of Northern Pacific larval species (Britt, L. L. *et al.*, 2001; Britt, L. L., personal communication) has been proposed involving contrast enhancement for chlorophyll-containing targets (McFarland, W. N. and Loew, E. R., personal communication). Whereas transparency seems to be an adaptive feature of zooplankton, most prey on chlorophyll-containing phytoplankton that can easily be seen through the otherwise transparent body (Figure 9). The increase in contrast, at least to our eyes, has led to the following generalizations:

1. In addition to an SWS1 and/or SWS2 opsin gene useful for both chlorophyll and UV contrast enhancement, diurnal larval planktivores in clear blue oceanic waters will express at least one longer-wave opsin gene that may or may not be turned off with age.
2. In addition to one or more longer-wave opsins, diurnal larval planktivores in green coastal or freshwater will express at least one SWS1 or SWS2 opsin gene useful for both chlorophyll and UV contrast enhancement that may or may not be turned off with age. These ideas were tested using the model of Loew E. R. and Zhang H. (2006).

Assume a single spherical target having a chlorophyll reflectance spectrum (Figures 9(b) and 9(c)) subtending 2° of visual angle and being viewed horizontally against the background spacelight at 2 m depth. The calculated background spectra are seen in Figure 10 for both clear oceanic (Figure 10(a), no dissolved chlorophyll or DOM) and a typical freshwater (Figure 10(b), 1 mg m^{-3} chlorophyll and 0.2 mg l^{-1} DOM). Using an iterative process, the program answers the question: which set of visual pigments maximizes the visibility of the target viewed against the spectrally defined background as the target is moved away from the eye? These solutions are seen in Figures 11 and 12 for clear blue oceanic water and a typical freshwater, respectively. For a straight luminosity task, a single visual pigment matching

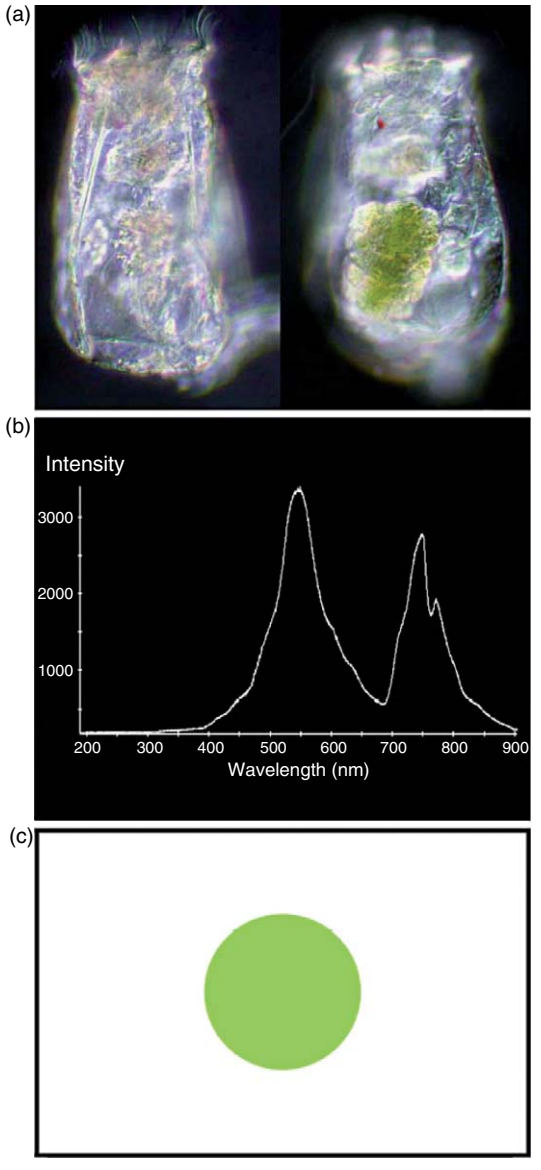

Figure 9 (a) A starved (left) and fed (right) rotifer showing the visibility of the chlorophyll-containing prey in the gut. (b) The reflectance spectrum of chlorophyll in the gut measured using an Ocean Optics USB 2000 spectroradiometer fitted to an Olympus microscope. (c) A colored target generated using the reflectance spectrum (see Loew, E. R. and Zhang, H., 2006, for methodology).

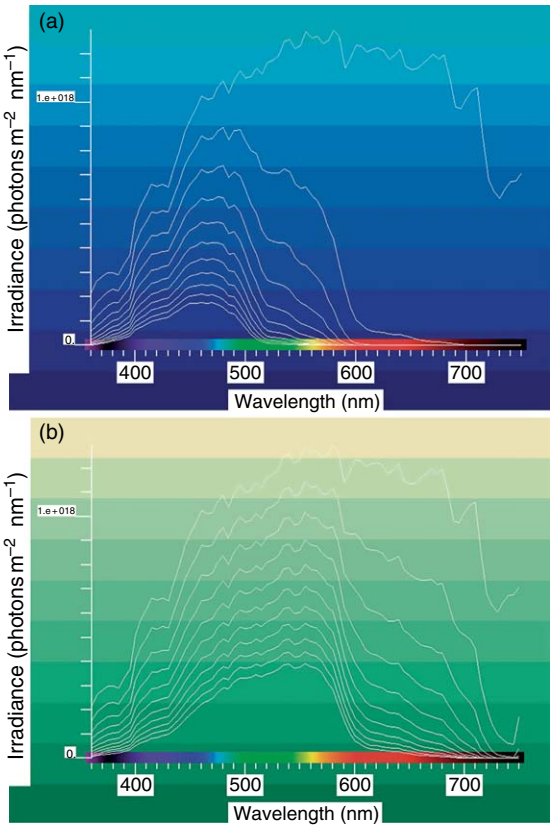

Figure 10 Calculated downwelling irradiance at 0.2 m intervals from the surface for (a) clear blue oceanic and (b) a typical freshwater. See text for explanation.

the background spacelight gives the best contrast as expected (Figures 11, 12(a), and 12(b)). For a chromaticity detection task, two pigments, one at long and the other at short wavelengths, provide the best contrast solution for this chlorophyll target (Figures 11, 12(c), and 12(d)). Note that in both water types the predicted LWS pigments should have λ_{max} greater than 600 nm to be optimal. The fact that pelagic species like tuna do not achieve this range may indicate an inability to utilize Vitamin A_2 as a chromophore. The predicted short wavelength pigments have somewhat longer λ_{max} than those measured in both freshwater and pelagic larvae. This may be due to a compromise between the need to use both chlorophyll and UV cues in prey detection.

The solutions given by this and most other models are best used for generating testable hypotheses as given above and should not be treated as reality. In addition to spectral data for the macro- and micro-environment and relevant targets in those environments, and the usual phenotypic data derived from MSP, electrophysiological or gene expression techniques, future studies should also include opsin genotype data, if a complete picture of the potential for color vision is to be derived.

Glossary

ankyrin repeats Protein-binding motifs.
Arr1 Arrestin 1.
Arr2 Arrestin 2.
ATP Adenosine 5′-triphosphate.
BAPTA 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid, fast Ca^{2+}-specific chelator.
Ca orange Calcium indicator.
Ca ATPase ATP-dependent Ca^{2+} pump.
CaCaM Ca^{2+} calmodulin.
***caged Ca*$^{2+}$** Photolabile compound with tightly bound Ca^{2+} which can be released by photolysis.
Calliphora Blowfly.
calnexin Gene encoding a Ca^{2+}-binding, chaperone protein.
calphotin Gene encoding a Ca^{2+}-binding protein.
CalX *Drosophila* sodium/calcium exchanger, belonging to NCX family.
CaM Calmodulin.
CaMKII Calmodulin kinase II.
CBS Calmodulin-binding site.
CC Coiled-coil region.
CDP–DAG Cytidine 5′-diphosphate–diacylglycerol.
CDP–DAG synthase Enzyme that converts PA into CDP–DAG.
cds Gene encoding CDP–DAG synthase.
cGMP Cyclic guanosine 3,5-monophosphate.
clathrin A major constituent of the protein coat of vesicles formed during endocytosis.
CMP Cytidine 5′-monophosphate.
CNG Cyclic nucleotide gated.
CTP Cytidine 5′-triphosphate.
DA Dark adapted.
DAG Diacylglycerol.
DAG lipase Enzyme that converts DAG into PUFAs.
DGK Diacylglycerol kinase.
diptera Flies which only have a single pair of wings on the mesothorax.
Drosophila Fruitfly.
***EC*$_{50}$** The half-maximal concentration for excitation.
eGFP Enhanced green fluorescent protein.
EGTA Ethylene glycol tetraacetic acid, a slow Ca^{2+} chelator.
ER Endoplasmatic reticulum.
ERG Electroretinogram.
Fluo-3 Calcium indicator.
FRET Fluorescence resonance energy transfer.
G Heterotrimeric G protein.
GAP GTPase-activating protein.
GDP Guanosine 5′-diphosphate.
GPRK1 G protein-coupled receptor kinase.
***G*$_q$** PLC-activating G protein.
GTP Guanosine 5′-triphosphate.
GTPase GTP-hydrolyzing protein.
***G*α** Heterotrimeric G protein alpha subunit.
***G*β** Heterotrimeric G protein beta subunit.
***G*γ** Heterotrimeric G protein gamma subunit.

IC_{50} The half-maximal concentration for inhibition.
immunogold labeling Antibody labeling using colloidal gold, visible in electron microscope.
ina *i*nactivation *n*o *a*fterpotential gene.
INAC Eye-specific PKC encoded by *inaC* gene.
INAD Scaffolding protein encoded by *inaD* gene.
INDO-1 Calcium indicator.
$InsP_3$ Inositol 1,4,5 trisphosphate.
$InsP_3R$ $InsP_3$ receptor.
ipRGC Intrinsically photosensitive retinal ganglion cells.
Kir2.1 PIP_2-sensitive inward rectifier ion channel.
LA Light adapted.
laza Lazaro, gene encoding LPP.
LIC Light-induced current.
Limulus Horseshoe crab.
LMC Large monopolar cells (first-order visual interneurons).
LPP Lipid phosphate phosphohydrolase.
M Metarhodopsin.
Na/K ATPase Sodium–potassium pump.
NCKX Potassium-dependent sodium/calcium exchanger.
NCX Na/Ca exchanger with 3Na:1Ca stoichiometry.
nina no inactivation no afterpotential gene.
NINAC Class III myosin.
norp no receptor potential gene.
NORPA Eye-specific PLC encoded by *norpA* gene.
ocelli Small, dorsally located simple eyes.
ommatidium Cluster of photoreceptor cells and accessory cells underlying each facet lens of the compound eye.
opsin Light-sensitive transmembrane G protein-coupled receptor.
P Ionic permeability.
PA Phospatidic acid.
PC Phosphatidylcholine.
PDA Prolonged depolarizing afterpotential.
PDZ domain (PSD95, disks large, zonula adherens) protein binding domain, five of which are found in the scaffolding protein INAD.
phosrestin Alternative name for arrestin.
PI Phosphatidylinositol.
Pi Phosphate.
PI kinase Enzyme that phosphorylates PI-producing PIP.
PI synthase Enzyme that converts CDP–DAG into PI.
PIP Phosphatidylinositol 4-phosphate.
PIP kinase Enzyme that phosphorylates PIP-producing PIP_2.
PIP_2 Phosphatidylinositol 4,5-bisphosphate.
PITP PI transfer protein.
PKA Protein kinase A.
PKC Protein kinase C.
PLC Phospholipase C.
PLCβ Phospholipase Cβ.
PLD Phospholipase D.
PUFA Polyunsaturated fatty acid.
quantum bump Single-photon response.
R Rhodopsin.
R1–6 Major class of fly photoreceptor cells.
R7 and 8 Minor classes of fly photoreceptor cells.
rdg retinal degeneration gene.
3-hydroxy retinal Chromophore of dipteran opsins.
3-hydroxy retinol Sensitizing pigment.
RGS Regulator of G protein signaling.
rhabdomere Light-absorbing structure of the photoreceptor cell.
RK Rhodopsin kinase.
RyR Ryanodine receptor.
scaffolding protein A protein that binds multiple other proteins of different types.
serotonin A monoamine neurotransmitter.
Shab Potassium channel gene.
Shaker Potassium channel gene.
Shal Potassium channel gene.
signalplex The INAD complex (also referred to as transducisome).
SMC Submicrovillar cisternae.
thapsigargin Endoplasmic reticulum Ca^{2+}-ATPase inhibitor.
TRP Light-activated nonspecific cation channel encoded by *trp* gene.
trp *t*ransient *r*eceptor *p*otential gene.
TRPL Light-activated nonspecific cation channel encoded by *trpl* gene.
trpl *t*ransient *r*eceptor *p*otential-*l*ike gene.
TRPγ TRP homologue.
UV Ultraviolet light.
WT Wild type.

1.05.1 Introduction

The task of encoding visual information poses photoreceptors with a number of formidable and often conflicting challenges. They must maximize their sensitivity, by being able to absorb a high fraction of the incident light; at the same time they may need to optimize visual acuity, by keeping the cross-sectional area of the light-capturing organelle close to the wavelength of light. Maximum sensitivity also requires the ability to detect single photons, reliably and as rapidly as possible. In addition, they must be able to light adapt in order to operate over the vast environmental range of intensities, which span more than 10 orders of magnitude from starlight to direct sunlight. In the course of evolution, two major classes of ocular photoreceptors have become specialized to perform these functions: ciliary photoreceptors, typified by vertebrate rods and cones (see Phototransduction in Rods and Cones), and the microvillar, or rhabdomeric photoreceptors of many invertebrate groups, including arthropods and most mollusks.

Ciliary and microvillar photoreceptors diverged very early in metazoan evolution (Arendt, D., 2003), and their separate evolutionary histories have resulted in rather different biological solutions to the challenges photoreceptors face. Although all known ocular photoreceptors use rhodopsin to absorb the incident light energy, and a G-protein-coupled signaling cascade to transduce this into changes in conductances in the plasma membrane, the detailed biochemical pathways are quite distinct. Where studied, the transduction cascade of ciliary photoreceptors leads to metabolism of cyclic GMP (cGMP) and modulation of cyclic nucleotide-gated ion channels (CNG channels), whilst microvillar photoreceptors use the more widespread phosphoinositide cascade, characterized by the effector enzyme phospholipase C (PLC) and activation of nonselective cation channels, probably often belonging to the transient receptor potential (TRP) superfamily. Perhaps not surprisingly, the two classes of photoreceptors have in many respects functionally converged; however, there are several intriguing differences in performance. Most notably perhaps, vertebrate eyes usually solve the problems of absolute sensitivity, speed of response and dynamic range by using two classes of photoreceptors: rods, which can detect single photons with limited temporal resolution, but which saturate at moderate photon fluxes; and cones, which cannot detect single photons, but which respond rapidly and can light adapt to signal under the brightest daylight intensities (see Phototransduction in Rods and Cones). By contrast, many invertebrate photoreceptors not only detect single photons, they often do so more rapidly than rods and yet can still light adapt to signal in full sunlight, when photon fluxes per photoreceptor can exceed 10^6 effectively absorbed photons per second. This chapter attempts to describe the cellular and molecular mechanisms that underlie this performance, concentrating on the photoreceptors of the fruit fly *Drosophila,* which has become the preferred model of invertebrate phototransduction, primarily because of its enormous potential for genetic manipulation and analysis (reviewed in Montell, C., 1999; Minke, B. and Hardie, R. C., 2000; Hardie, R. C. and Raghu, P., 2001; Pak, W. L. and Leung, H. T., 2003). After introducing the structural and electrophysiological framework we consider the various molecular components and how they are regulated. We end by attempting to summarize our current understanding of the molecular strategies underlying the excitation and adaptation, and finally provide a brief overview of phototransduction mechanisms in some other invertebrate preparations.

1.05.2 Photoreceptor and Retinal Morphology

Rhodopsin is a transmembrane protein, and in order to maximize absorption of incident light most photoreceptors have evolved structures to increase the surface area of light-absorbing membrane. In vertebrate rods, these are the rod outer segments (ROS) consisting of stacks of internalized membranous disks. Many invertebrates, including arthropods and mollusks, utilize rhabdomeres, which consist of tightly packed arrays of microvilli. Rhabdomeres in *Drosophila* consist of ~30–50 000 microvilli, each 1–2 μm long and 60 nm in diameter (Figure 1). They develop from the apical surface of the cell to which they are attached by a narrow neck. Each microvillus contains ~1000 rhodopsin molecules closely packed in the microvillar membrane at a density of ~4000 μm^{-2}. Together, the microvilli form the rhabdomere, a 80- to100-μm-long and 1- to 2-μm-diameter tapering rod-like structure, which functions as a waveguide, trapping some 50% of the incident axial light at the wavelength of peak absorption (reviewed in Hardie, R. C., 1985).

Eight such photoreceptors are assembled in a so-called ommatidium behind each of the ~750 facets of the *Drosophila* compound eye. In cross section, the rhabdomeres form a precise hexagonal array with six

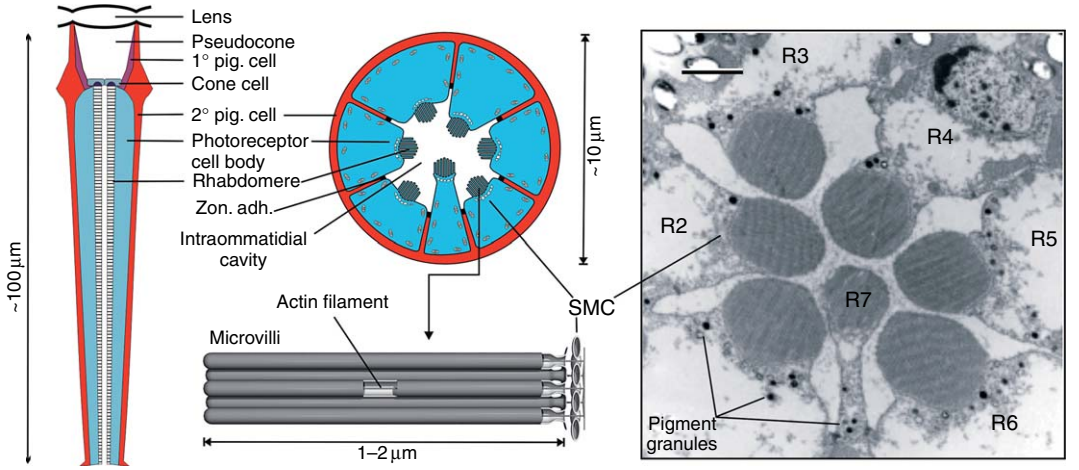

Figure 1 Photoreceptor and retinal morphology in *Drosophila*. Left: Schematic of ommatidium showing the photoreceptors with the microvillar rhabdomeres, surrounded by secondary pigment cells. Light is focussed on the rhabdomere tips by the overlying lens through the pseudocone. The pseudocone is filled with fluid secreted by the underlying cone cells (Semper cells), and surrounded by primary pigment cells. The schematic cross section shows the hexagonal array of rhabdomeres, projecting into the intraommatidial cavity. The central photoreceptor is R7 (an ultraviolet (UV) receptor), the rest are R1–6 cells. The eighth photoreceptor R8, whose rhabdomere is contiguous with that of R7, lies proximally in the ommatidium. The photoreceptors are connected by specialized junctions, called zonula adherens, or desmosomes, which separate the apical (medial) membrane of the cell from the basolateral membrane. The detailed schematic (below) shows how the rhabdomere is formed from tightly packed microvilli, with a system of submicrovillar cisternae (SMC) lining their base. Right: The electron micrograph shows the six R1–6 cells with large rhabdomeres and the central R7 cell; pigment granules can be seen close to the base of the rhabdomeres. Scale bar = 1 µm.

peripheral rhabdomeres (R1–6) all containing the same visual pigment (Rh1 with $\lambda_{max} = 480$ nm), and a central tiered rhabdomere (R7 in the distal two thirds of the ommatidium, R8 in the proximal third). R7 and R8 cells have a variety of visual pigments (λ_{max} ~340, 370, 440, and 510 nm), which subserve the fly's color vision. As far as is known, the basic mechanism of phototransduction is the same in the different classes of photoreceptors, and apart from the rhodopsins, there appear to be no cell-specific isoforms of the various component of the transduction cascade as is the case in vertebrate rods and cones (see Phototransduction in Rods and Cones). However, the majority of studies have been performed on the major class of photoreceptors, R1–6.

The rhabdomeres project toward the center of the ommatidium into a large extracellular space (the intraommatidial cavity), delimited by specialized junctions (desmosomes, or zonula adherens) between neighboring photoreceptors. Photoreceptors are derived from epithelial cells, and these junctions separate the apical (rhabdomere and stalks) membrane from the basolateral membrane, which forms the outer surface of the photoreceptor cluster (Figure 1). Unlike tight junctions, desmosomes do not represent a diffusion barrier between the intraommatidial cavity and the rest of the extracellular space (Chi, C. and Carlson, S. D., 1981). Completing the ommatidium are a number of accessory cells: four distal cone, or Semper cells, that form the floor of the fluid-filled transparent pseudocone, which forms the optical path between the rhabdomere tips and the facet lens; two primary pigment cells, which surround the distal ends of the photoreceptors and form the walls of the pseudocone, and 12 secondary and tertiary pigment cells, shared between ommatidia (Ready, D. F., 1989). Also referred to as pigmented glia, the pigment cells surround the photoreceptors, optically isolating the ommatidia over the depth of the retina. At the base of the retina, the R1–6 photoreceptors project short axons to the first neuropile (lamina), where they form histaminergic synapses with second-order cells, the large monopolar cells (Hardie, R. C., 1989; Sarthy, P.V., 1991). The microvilli contain no internal membranous structures; however, each contains a central F-actin filament. With appropriate fixation, the actin filament can be seen to be connected to the microvillar membrane via sidearms (see Figure 6), which may be formed by the class III unconventional myosin NINAC (Kumar, J. P. and Ready, D. F., 1995; Hicks, J. L. *et al.*, 1996). Closely apposed (10 nm) to the base of the microvilli, is an array of submicrovillar cisternae (SMC), which

are derived from smooth endoplasmic reticulum (ER). These have been considered to represent internal Ca^{2+} stores, and similar, more extensively developed structures in many arthropods (including bee and *Limulus*) mediate light-induced Ca^{2+} release (see Section 1.05.9, reviewed in Nasi, E. *et al.*, 2000). However, in *Drosophila* and many other Diptera, the SMC are much reduced in size with a very narrow lumen and it is questionable whether they perform any significant role in the release of Ca^{2+} (Section 1.05.6.1). They effectively form a fenestrated double-layered membranous curtain lining the bases of the microvilli and they may be more important as a site for PI recycling (Section 1.05.7), and also perhaps as a diffusion barrier or baffle between the rhabdomere and the rest of the cell.

The cell body contains numerous ~0.1 μm pigment granules, which migrate toward the rhabdomere in response to light, functioning as a cell autonomous pupil. Since the rhabdomere acts as a waveguide, a significant fraction of the light actually travels outside its perimeter (evanescent wave). The pupil pigment granules can therefore effectively bleed light from the rhabdomere, thereby attenuating up to 90–99% (Roebroek, J. G. H. and Stavenga, D. G., 1990) of the incident light. The pupil also significantly improves spatial resolution by narrowing the acceptance angle, whilst causing a blue shift in the spectral sensitivity (Hardie, R. C., 1979; Stavenga, D. G., 2004). Pupil pigment migration, which is intensity dependent, occurs over a time course of ~5 s following onset of illumination. The exact mechanism remains obscure, but it is Ca^{2+} dependent (Kirschfeld, K. and Vogt, K., 1980), and since it can be readily monitored with optical techniques in the intact animal, it can be used as an *in vivo* measure of photoreceptor performance and Ca^{2+} signaling (e.g., Hofstee, C. A. and Stavenga, D. G., 1996).

The immediately obvious function of the rhabdomeric structure is to provide the light capturing waveguide required for maximizing absorption whilst preserving spatial sensitivity. The parallel arrays of microvilli also provide the rhabdomere with an intrinsic dichroism, which forms the basis for the ability of arthropods and mollusks to detect and discriminate polarized light (Wehner, R., 1989). In addition, the microvillar structure is also the key to understanding many aspects of the photoreceptors' performance (see Section 1.05.8). All the major components of the transduction cascade, from rhodopsin to the light-sensitive channels are localized in the microvillus, and it seems likely that the immediate effect of single-photon absorption is more or less limited to activation of enzymes and channels in the microvillus where it was absorbed. This extreme compartmentalization is crucial for the rapid kinetics of the response to light, as it minimizes diffusional delays, and also greatly increases the effective concentration of molecular components and metabolic intermediates in the transduction cascade (see Section 1.05.8). For example, within the volume of one microvillus, just a single molecule represents a concentration of ~1 μM; whilst the average resting concentration of free Ca^{2+} (100–200 nM) would represent just one-quarter of a Ca^{2+} ion in solution at any one instant!

1.05.3 Electrophysiology

1.05.3.1 Invertebrate Photoreceptors Depolarize

Ever since the first photoreceptor intracellular recordings in the 1960s, it has been known that vertebrate photoreceptors hyperpolarize in response to light due to closing of cation channels, whilst most invertebrate ones depolarize. Under many conditions, this difference may be of minor functional significance, since both types of photoreceptors signal via graded potentials and under most situations are responding to fluctuations of intensity (contrast) around a mean background. However, there are important implications under certain conditions, such as the ability to detect single photons. In rods, there are ~10^4 channels open in the dark, and a large number need to be closed to make significant difference. Thus, a typical quantum bump in a vertebrate rod represents the closing of ~200 channels, generating a response of ~1 pA (see Phototransduction in Rods and Cones). By contrast, in microvillar photoreceptors the channels are closed in the dark, membrane resistance is at its highest, and only a few channels may need to be opened to generate a significant depolarization. Indeed, in *Drosophila* only ~15 channels are activated during a quantum bump (Henderson, S. R. *et al.*, 2000), generating a 10 pA current and a voltage response of ~1–2 mV in the intact eye (Wu, C. F. and Pak, W. L., 1978; Johnson, E. C. and Pak, W. L., 1986).

1.05.3.2 Voltage-Clamped Light-Induced Current

Because of their small size, intracellular recordings from *Drosophila* photoreceptors are technically challenging (see Section 1.05.3.4); however, it has also proved possible to record from single photoreceptors

using whole-cell patch clamp techniques from dissociated ommatidia of both pupae and young adults. This preparation, developed independently in two laboratories (Hardie, R. C., 1991a; 1991b; Ranganathan, R. *et al.*, 1991), allows isolation of the light-induced current (LIC) with excellent recording quality, whereby responses to single photons, single G proteins, and even single channels can be clearly resolved. This preparation, in combination with the molecular genetic potential of *Drosophila*, has been particularly important for recent advances in our mechanistic and quantitative understanding of phototransduction.

In the dark, photoreceptors have a resting potential of ~−70 to −80 mV, which is close to the potassium equilibrium potential (−85 mV) under standard recording conditions. The cells have a high input resistance (~2 GΩ) and a large capacitance (~60 pF), the majority (>80%) of which can be attributed to the surface area of the microvillar membrane. This results in a slow membrane time constant (12 ms for the dark-adapted (DA) values above), but intracellular recordings in the intact animal suggest that the membrane properties do not compromise the temporal resolution of even DA responses in the voltage domain, and may even be advantageous in filtering out high-frequency noise (Juusola, M. and Hardie, R. C., 2001).

An ongoing barrage of ~2 pA events at rates of 1–4 s^{-1} can be resolved in complete darkness (Figure 2), which is eliminated in mutants of the G protein α subunit and therefore probably represents activation of the cascade by spontaneous activation of single G proteins (Hardie, R. C. *et al.*, 2002). Recent evidence indicates that the rate is only kept this low by the presence of approximately twofold excess of G protein β subunits, and, the spontaneous dark noise is greatly increased in heterozygote mutations of Gβ when there are approximately equal numbers of β and α subunits (Elia, N. *et al.*, 2005). Much more rarely, random thermal rhodopsin isomerizations generate spontaneous quantum bumps at rates of less than 1 min^{-1} (Henderson, S. R. *et al.*, 2000).

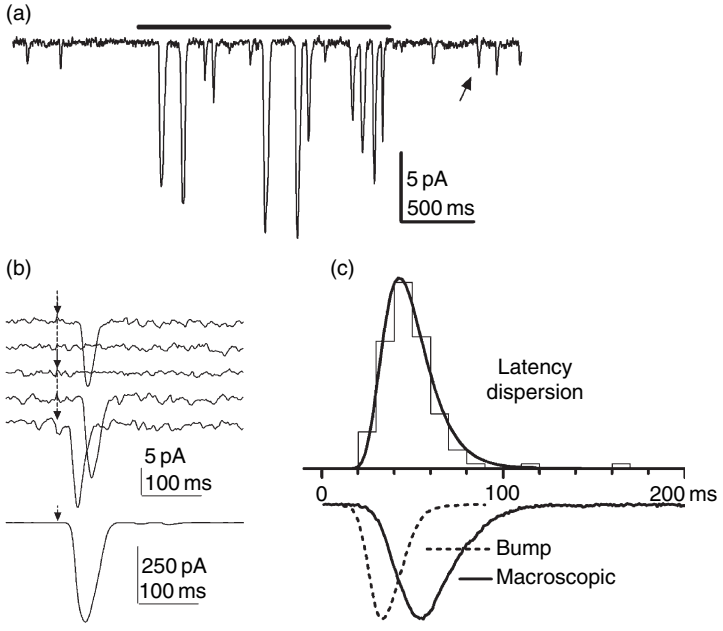

Figure 2 Quantum bumps. (a) Response of a whole-cell voltage-clamped photoreceptor to 2 s of dim illumination (~2 effectively absorbed photons per second, bar). In the dark, small ~2 pA events (e.g., arrow) are likely to represent spontaneous activation of single G proteins. Light induces a train of ~10 pA quantum bumps. (b) Responses to brief (1 ms) flashes (arrows), containing on average 0.5 effective photons. Some flashes induce no response (failures), others induce single quantum bumps with a variable latency; below, the macroscopic response of the same cell to a flash containing ~100 photons is broader than the individual quantum bumps. (c) Top: latency distribution (histogram) of quantum bumps elicited by brief flashes (as in (b)); below, normalized waveforms of quantum bump and macroscopic response. The smooth curve in the top trace, obtained by mathematically deconvolving the two waveforms, is an excellent fit to the latency distribution, confirming that the waveform of the macroscopic response represents the convolution of the bump latency distribution and bump waveform (Hardie, R. C; unpublished data; for further details, see Henderson, S. R. *et al.*, 2000).

With dim illumination individual quantum bumps can be clearly resolved (Figure 2). Strict adherence to Poisson statistics, as well as frequency of seeing curves, indicate that these represent responses to single-photon absorptions (Wu, C. F. and Pak, W. L., 1975; Henderson, S. R. *et al.*, 2000). The quantum bumps have a mean amplitude of ~10 pA (range ~2–20 pA) representing the simultaneous opening of ~15 channels. This is consistent with the opening of channels in a single microvillus, which, according to quantitative biochemical estimates in the larger fly *Calliphora*, should contain about 25 channels (Huber, A. *et al.*, 1996a). Quantum bumps have a duration (halfwidth) of ~20 ms and are generated with a characteristically variable latency of between ~20 and 100 ms (mean ~40–50 ms). Consequently, the waveform of the macroscopic response to brief flashes represents the convolution of the bump waveform and its latency dispersion. Unlike the situation in rods, voltage-clamped quantum bumps sum linearly over a large range, and the macroscopic response to brief flashes containing up to at least several hundred photons can be accurately reconstructed from the linear superposition of the underlying bumps (Henderson, S. R. *et al.*, 2000). The essential kinetic description of the DA flash response is thus embodied in the bump waveform and its latency distribution (Figure 2).

With longer steps of light, the bumps fuse to form a noisy maintained inward current, and as the intensity increases there is an increasingly rapid transition from peak to plateau representing the onset of light adaptation. At higher intensities this overshoots giving rise to what is effectively a damped oscillation (Figure 3(d)). Peak responses can greatly exceed 20 nA, but are not accurately voltage-clamped, whilst the steady-state plateau saturates at ~500 pA. Increments of intensity superimposed upon maintained backgrounds elicit responses with the classic features of light adaptation (Figure 4): gain is decreased as a function of background intensity, whilst the kinetics are significantly accelerated. In the current (voltage-clamped) domain, the shift of the response along the intensity (I) axis with light adaptation can simply be described as multiplicative reduction in gain (Gu, Y. *et al.*, 2005); in the voltage

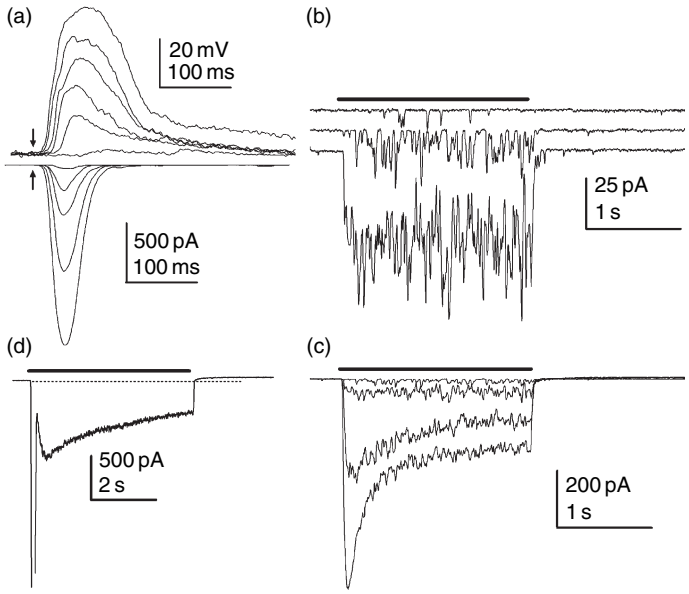

Figure 3 Whole-cell recordings of light responses in *Drosophila* photoreceptors. (a) Lower traces: Voltage-clamped responses recorded by whole-cell patch clamp from a dissociated ommatidium to brief (1 ms) flashes of increasing intensity (~5 to ~500 effective photons): responses in this range scale linearly with intensity. Upper family of traces: voltage recordings in current clamp mode from the same cell. (b–c) Responses to 2 s steps of light of increasing intensity (note different scales in (b) and (c)): bumps fuse to form noisy inward currents, which then show an increasingly rapid peak–plateau transition as intensity increases ((b): 3, 30, and 300 photons per second; (c) 30, 300, 3000, and 18 000 photons per second). This transition is a direct manifestation of light adaptation. (d) Response to a bright stimulus (3×10^5 photons per second), approximating daylight intensities: the peak response (>10 nA and off-scale) rapidly adapts, generating a notch before reaching a plateau that then slowly relaxes to the final steady-state level. After light off, there is a small outward current due to the electrogenic Na^+/K^+ ATPase (Hardie, R. C., unpublished data).

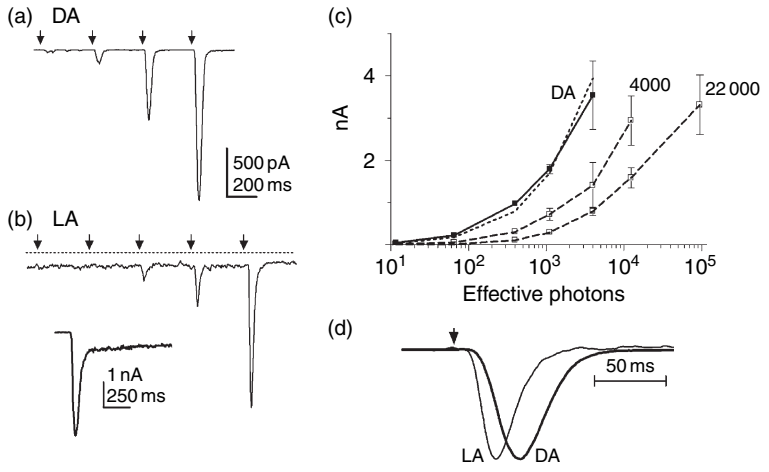

Figure 4 Light adaptation. (a) and (b) Voltage-clamped responses to brief (1 ms) flashes of increasing intensity in the dark, and the same flashes superimposed on a maintained background of ~22 000 effectively absorbed photons per second, generating a plateau response of ~150 pA (dotted line shows zero current). Inset shows the onset of the adapting light. (c) Response intensity functions from recordings, similar to those shown in (a) and (b), in dark-adapted (DA) and light-adapted (LA) states (intensity in effective photons per second). The DA response intensity function is accurately reproduced by simple linear scaling of a LA response intensity function (dotted line), indicating that light adaptation at this level can be simply described by a multiplicative reduction in gain. (d) Normalized flash responses of DA and LA responses show the acceleration in kinetics typical of light adaptation. Adapted from Gu, Y., Oberwinkler, J., Postma, M., and Hardie, R. C. 2005. Mechanisms of light adaptation in *Drosophila* photoreceptors. Curr. Biol. 15, 1228–1234, with permission.

domain, this translates into a more complex behavior (shifted $V/\log I$ functions, slope increasing with intensity) due to the passive and voltage-dependent properties of the membrane.

1.05.3.3 Potassium Channels

In the voltage domain, the overall response is further shaped by passive membrane properties, as well as a variety of voltage-sensitive conductances and electrogenic transporters. Dominant amongst these are at least four classes of potassium channels, which play important, though often subtle roles in shaping the voltage response.

1. A very rapidly activating and inactivating A current, I_A, encoded by the prototypical voltage-gated K^+ channel gene, *Shaker* (Hardie, R. C., 1991a; Hardie, R. C. *et al.*, 1991). The voltage operating range of this current is more negative (V_{50}act = −24 mV) than for other reported *Shaker* currents, though it can be shifted to a more positive range by serotonin (Hevers, W. and Hardie, R. C., 1995). Modeling and intracellular recordings from photoreceptors in the intact animal suggest that the voltage dependence of the so-called window current, representing the overlap of the steady-state activation and removal from inactivation voltage dependences, can effectively amplify voltage signals and thus results in a significant improvement in the information capacity (Niven, J. E. *et al.*, 2003). The *Shaker* channels are densely expressed on the outer (basolateral) membrane of the photoreceptors and are almost always encountered at high density in cell-attached patch recordings (Hardie, R. C., 1991a).
2. A slowly activating delayed rectifier, I_{Ks} (Hardie, R. C., 1991a), which is encoded by the *Shab* gene (Vahasoyrinki, M. *et al.*, 2006). Although generating similar sized currents to I_A, I_{Ks} channels are only very rarely encountered in cell-attached patch recordings, suggesting they have a different localization, possibly on the apical membrane. I_{Ks} has a more positive voltage operating range than I_A (V_{50} act = ~0 mV) and inactivates much more slowly with a time constant of ~1 s. This is the dominant maintained outward current at depolarized potentials, which would be predicted to counteract the depolarization and help prevent saturation. Interestingly, the *Shab* conductance is only expressed in R1–6, but not in R7 and R8 cells (Anderson, J. and Hardie, R. C., 1996).
3. A fast delayed rectifier, I_{Kf} with intermediate kinetics (inactivation $\tau \sim 50$ ms) and a slightly more negative operating range than I_A. From its properties, I_{Kf} is most likely encoded by *Shal*. This

conductance is found in R1–6, R7, and R8, but is not uniformly expressed, and is entirely lacking in some cells (Hardie, R. C., 1991a; Vahasoyrinki, M. *et al.*, 2006). One may speculate that it fine tunes the kinetics of the voltage output and may be expressed preferentially in certain eye regions with specific demands on temporal resolution.

4. A very slowly activating and noninactivating K current which has been revealed in *Sh;Shab* double mutants (Vahasoyrinki, M. *et al.*, 2006).

In addition, the photoreceptors may express two classes of Ca^{2+}-activated K channels (*Slo* and *Sk*), and preliminary data using intracellular voltage recording in the intact animal suggest that mutants lacking these channels have subtle defects in their peak-to-plateau transition (Wolfram, V., 2004).

1.05.3.4 Other Channels and Transporters

As well as K^+ channels, the photoreceptors also express a noninactivating voltage-gated Ca^{2+} conductance, which can be recorded in the cell body, but is presumably more important in synaptic release at the photoreceptor axon terminal (Hardie, R. C. and Mojet, M. H., 1995; Anderson, J. and Hardie, R. C., 1996). In addition, the photoreceptors exhibit inward rectification due to a hyperpolarization-activated chloride current (Hardie, R. C. and Minke, B., 1994b), recently characterized in detail by Ugarte G. *et al.* (2005), who suggest it is encoded by *clc-2*.

Finally, the photoreceptors express at least two electrogenic transporters:

1. A Na^+/K^+ ATPase, which is expressed predominantly on the basolateral surface of the cell away from the rhabdomere (Yasuhara, J. C. *et al.*, 2000). It generates an outward current (or afterhyperpolarization in the voltage domain) following bright stimulation (e.g., Figure 3) and can make a significant contribution to the depolarized plateau potential level (Jansonius, N. M., 1990).
2. An electrogenic Na^+/Ca^{2+} exchanger (*calx* gene), which is predominantly expressed in the microvillar membrane, and which can generate currents of up to ~100 pA (Hardie, R. C., 1995; Wang, T. *et al.*, 2005b). Belonging to the NCX family (Schwarz, E. M. and Benzer, S., 1997), it represents the dominant mechanism of Ca^{2+} extrusion, and plays an essential role in clearing the Ca^{2+} influx associated with the light-sensitive current (Wang, T. *et al.*, 2005b) (see also Section 1.05.6.1.2). A second, K^+-dependent Na^+/Ca^{2+} exchanger gene (NCKX) has also been reported to be expressed in the photoreceptors (Haug-Collet, K. *et al.*, 1999), but has not been detected electrophysiologically (Wang, T. *et al.*, 2005b).

1.05.3.5 Intracellular Recordings of Voltage Responses

Intracellular recordings of photoreceptors in the intact animal are demanding, and values for resting potential, and input resistance may often be underestimated due to the shunt resistance introduced by electrode penetration. The best recordings report resistances of up to ~200–500 MΩ, and resting potentials of ~−70 mV (Juusola, M. and Hardie, R. C., 2001). Apart from the shunt resistance, the difference between these values and values recorded in dissociated cells may also reflect the contribution from the axon terminal, which is severed during the dissociation. Thus, recent evidence suggests there is a significant depolarizing synaptic feedback at the receptor terminal, and when synaptic transmission was blocked by warming the temperature-sensitive *shibire* mutation, the photoreceptors hyperpolarized by a further 10–15 mV (Zheng, L. *et al.*, 2006). Responses to brief flashes show broadly similar kinetics to the LIC, but are slightly faster in rise time with a more skewed waveform; quantum bumps of ~1–2 mV can be resolved with dim illumination (Wu, C. F. and Pak, W. L., 1975; 1978). As in most arthropod photoreceptors, saturating responses reach ~70 mV, close to the reversal potential of the light-sensitive channels, with a maintained plateau of ~30 mV above resting potential. V/log I curves are sigmoidal, covering 4–5 log units of intensity with a log-linear region of ~2 log units.

Photoreceptors in wild type (WT) flies light adapt and continue responding to contrast fluctuations up until at least 10^6 effectively absorbed photons per second, equivalent to vision under the brightest daylight conditions. Contrast sensitivity and temporal resolution improve with light adaptation, allowing transmission of signals up to ~100 Hz (3 dB cutoff at 25 Hz) with an information capacity of ~200 bits per second at 25 °C (Juusola, M. and Hardie, R. C., 2001).

1.05.3.6 Electroretinogram

Extracellular electroretinogram (ERG) recordings can be made straightforwardly with an electrode placed on the surface of the cornea (Figure 5). The

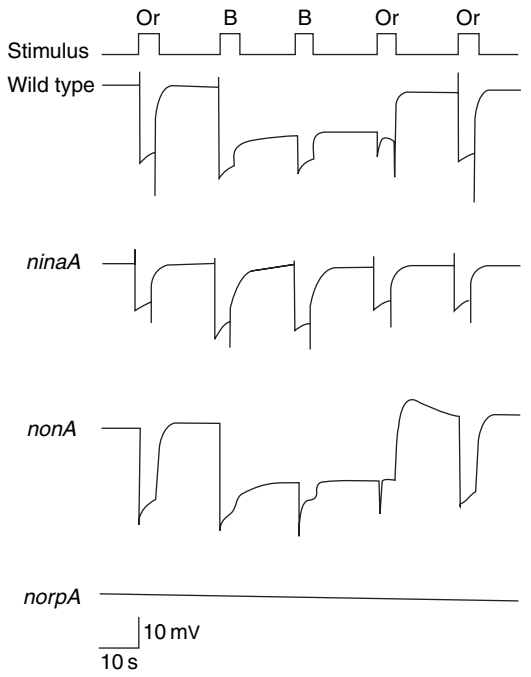

Figure 5 Electroretinogram (ERG) recordings. In a wild-type (WT) fly a 5 s pulse of orange light elicits a typical ERG with on and off transients and a maintained corneal negative component. At light off, the potential returns rapidly to baseline; however, a blue stimulus which converts >50% of R to M, creates a prolonged depolarizing afterpotential (PDA), whilst a second blue test flash elicits a much reduced (inactivated) response lacking the transients, and which is primarily mediated by the R7 cells. A subsequent orange stimulus, which reconverts M to R, terminates the PDA and restores sensitivity. In the *no inactivation no afterpotential* mutant, *ninaA*, there is no PDA and no loss of sensitivity (inactivation) to the second blue test flash. This is the classical *nina* phenotype found in a variety of mutants that have low levels of rhodopsin (*ninaA* encodes a chaperone required for rhodopsin folding and targeting). The *nonA* mutant lacks the on and off transients, but is otherwise normal, suggesting a defect in synaptic transmission. The *norpA* mutant (encoding PLC) has no detectable response. Reproduced with permission from Pak, W. L. 1995. *Drosophila* in vision research: the Friedenwald lecture. Invest. Ophthalmol. Vis. Sci. 36, 2340–2357.

ERG represents the summed activity of all the photoreceptors, and also higher-order neurons and glial cells. The sustained corneal negative component of the response is maximally ~20–30 mV. It is normally attributed to the photoreceptors, although experiments using a perfused preparation suggest caution in interpretation, since with bright light, slow components in particular may become dominated by depolarization of the pigmented glia (secondary pigment cells) by the build up of extracellular K^+ (Minke, B., 1982; Minke, B. and Selinger, Z., 1992). Nevertheless, it reflects indirectly at least the photoreceptor response and has been widely used as an easily recorded measure of photoreceptor output. The ERG also has rapid on (positive) and off (negative) transients, which reflect the activity of the second-order interneurons (large monopolar cells or LMCs) which have an amplified and transient response of inverted polarity due to sign-inverting synapses using the photoreceptor neurotransmitter, histamine, which activates histamine-gated chloride channels on the LMCs (Hardie, R. C., 1989).

1.05.4 Molecular Components of the Phototransduction Cascade

1.05.4.1 Strategies for Gene Discovery

The discovery and characterization of the molecular components of the transduction cascades in vertebrates and invertebrates (Figures 6 and 7) exploited two very different approaches. In vertebrates the ability to isolate ROS *en masse*, particularly from bovine retina, greatly facilitated the purification, and subsequent molecular identification of the elements of the cascade (see Phototransduction in Rods and Cones). In invertebrates, discovery relied in the first instance on classical forward genetic approaches in *Drosophila* to identify and positionally clones genes involved in phototransduction. The pioneers in this enterprise, starting in the late 1960s were Seymour Benzer (Hotta, Y. and Benzer, S., 1970) and Bill Pak (Pak, W. L. *et al.*, 1970). Benzer had a wider agenda, wanting to identify genes involved in vision generally, and thus isolated behavioral mutants defective in phototaxis. Pak was more focussed on the early events in vision and embarked upon a labor intensive, but ultimately rewarding electrophysiological screen to detect subtle defects using the readily recorded ERG.

At least 50 different complementation groups representing distinct genes were isolated. Some 30 of these had defects in the ERG transients and represent genes involved in synaptic transmission or responses of second-order neurons. Most of the remainder have turned out to be photoreceptor genes, many of which are directly involved in the transduction cascade (Table 1; reviewed in Pak, W. L., 1995; Pak, W. L. and Leung, H. T., 2003). A number of important genes were not discovered in these early screens, but were identified by molecular

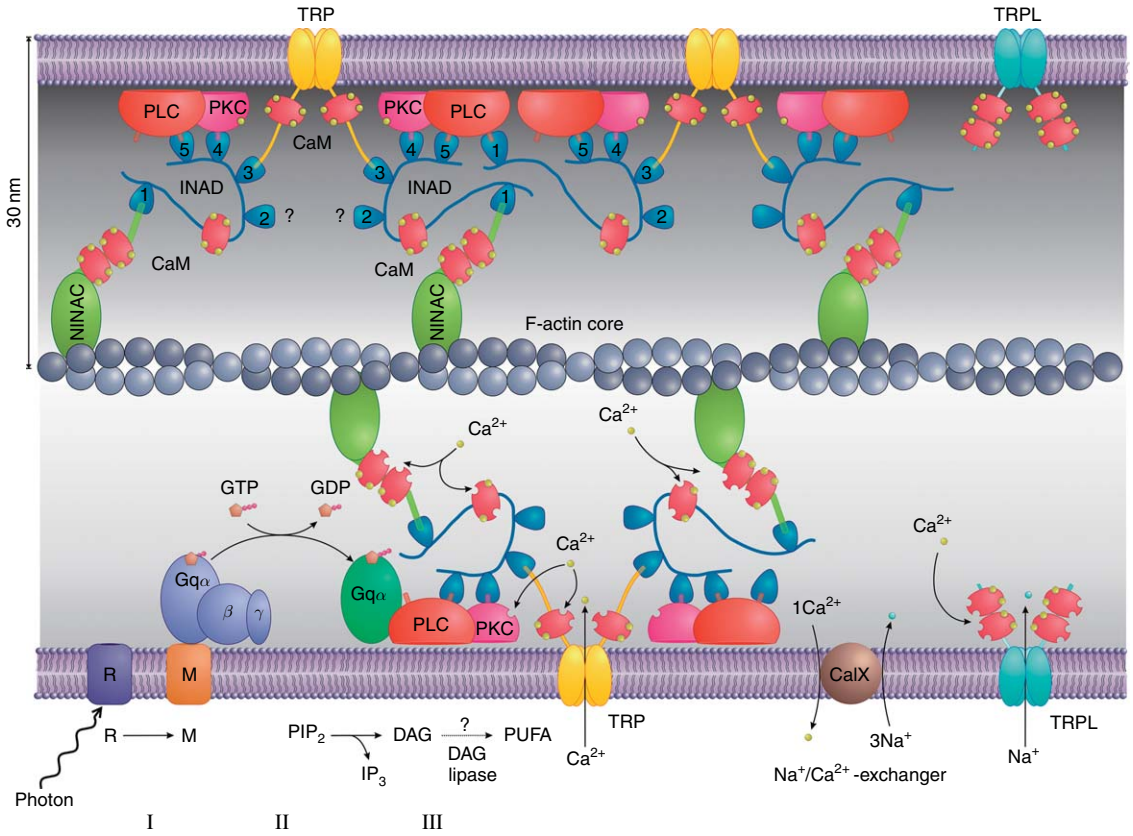

Figure 6 Overview of the phototransduction cascade in *Drosophila*. Lower half: (I) Photoisomerization of rhodopsin (R, encoded by *ninaE* gene) to metarhodopsin (M) activates G_q via GTP–GDP exchange, releasing the $G_q\alpha$ subunit (*Gαq* gene); (II) $G_q\alpha$ activates phospholipase C (PLC, *norpA* gene), generating $InsP_3$ and DAG from PIP_2. DAG is also a potential precursor for polyunsaturated fatty acids (PUFAs) via DAG lipase; although PUFAs can activate the channels, there is no direct evidence for this enzyme in the cascade. (III) Two classes of light-sensitive channels (*trp* and *trpl* genes) are activated by an unknown mechanism. TRP is primarily Ca^{2+} permeable; Ca^{2+} influx feeds back at multiple sites, including calmodulin (CaM), which itself has multiple targets, and PKC (see Section 1.05.6, Table 3). Ca^{2+} is extruded by the CalX Na^+/Ca^{2+} exchanger. All components drawn approximately to scale within a schematic microvillus. Upper half: Several components of the cascade, including TRP, protein kinase C (PKC, *inaC* gene), and PLC are assembled into a signaling complex by the scaffolding protein, INAD, which may be linked to the F-actin core via the NINAC class II myosin. The INAD protein contains five PDZ domains (1–5) joined by short linker regions. Each PDZ domain associates preferentially with different targets (Huber, A. *et al.*, 1996a; Shieh, B. H. and Zhu, M. Y., 1996; Chevesich, J. *et al.*, 1997; Tsunoda, S. *et al.*, 1997; Xu, X. Z. S. *et al.*, 1998). The precise composition of the native complex is uncertain as some PDZ domains are reported to bind at least two different targets, and there are several possibilities for multimerization: by homophilic interactions between INAD (PDZ domains 3 and 4) (Xu, X. Z. S. *et al.*, 1998); involvement of up to four TRP subunits and linkage of two INAD molecules via PLCβ which is reported to bind both PDZ1 and PDZ5 (van Huizen, R. *et al.*, 1998). Several of these scenarios are depicted in the figure. CaM binds to the linker region between PDZ1 and PDZ2 (Xu, X. Z. S. *et al.*, 1998) and also to NINAC, TRP, and TRPL.

approaches, such as subtractive hybridization and/or homology to vertebrate genes. Mutants of several these, including arrestin (Dolph, P. J. *et al.*, 1993), G protein (Scott, K. *et al.*, 1995), and the TRPL light-sensitive channels (Niemeyer, B. A. *et al.*, 1996), were generated in a second wave of mutagenesis based on antigenicity, that is, using antibodies to screen for mutants generated by random chemical mutagenesis lacking the proteins in question (see also Koundakjian, E. J. *et al.*, 2004).

1.05.4.2 Rhodopsin

The *n*o *i*nactivation *n*o *a*fterpotential E (*ninaE*) mutant was isolated by Pak and coworkers using the ERG screen (Figure 5). Even before it was cloned, it

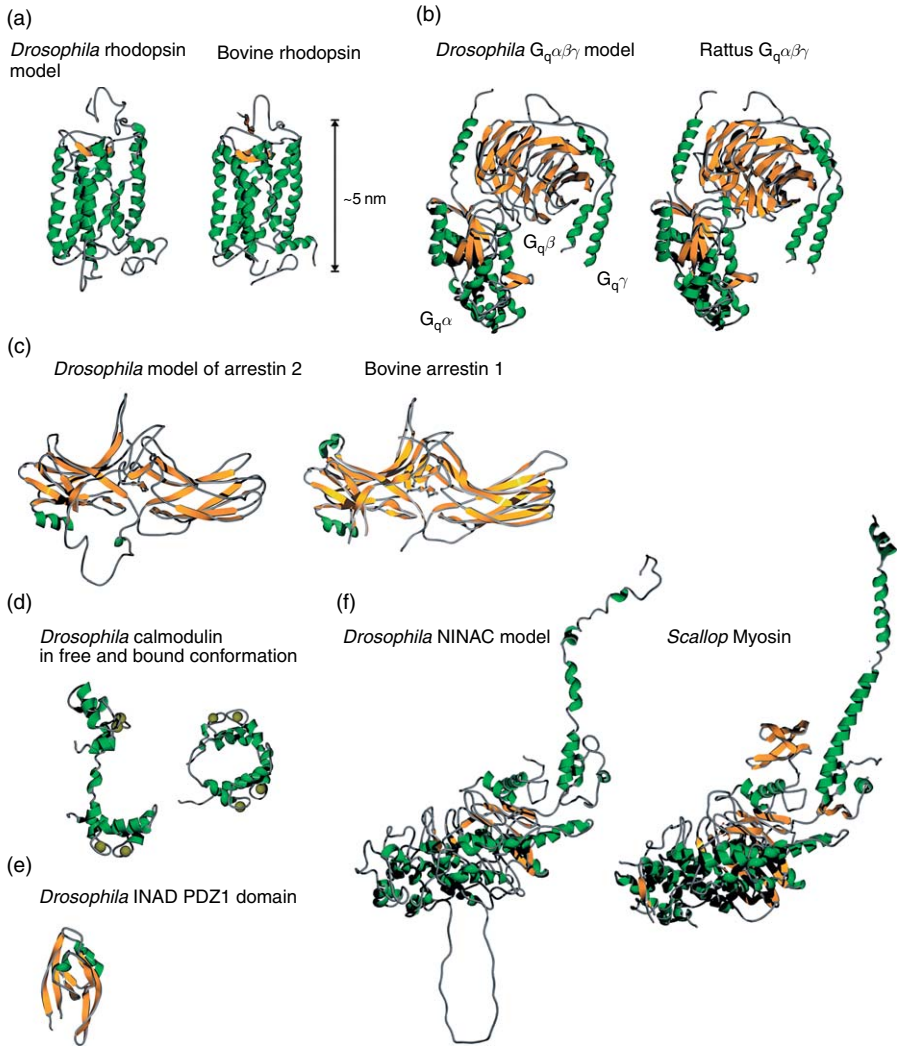

Figure 7 Molecular models of some key transduction proteins. Modeled protein structures of several proteins involved in fly phototransduction based on solved crystal structures of homologous proteins. (a) The solved structure of bovine rhodopsin (left structure, 1F88) was used to model *Drosophila* rhodopsin (*ninaE*). (b) Vertebrate (*Rattus*, 1GP2) G_q was used to model the structure of *Drosophila* G_q. (c) Bovine arrestin 1 (1G4R) was used to model the structure of *Drosophila* arrestin 2. (d) Structure of free and α-helix-bound *Drosophila* CaM (4CLN, 2BBN). (e) Structure of the first PDZ domain (PDZ1, 1IHJ) of *Drosophila* INAD, the other four PDZ domains have similar sizes (1IHJ). (f) Structure of single-headed scallop myosin (1B7T) used to model *Drosophila* NINAC. The models were generated using Geno3D (Geourjon, C. *et al.*, 2001; Combet, C. *et al.*, 2002). References: 1F88 (Palczewski, K. *et al.*, 2000); 1GP2 (Wall, M. A. *et al.*, 1995); 1G4R (Han, M. *et al.*, 2001); 1B7T (Houdusse, A. *et al.*, 1999); 4CLN (Taylor, D. A. *et al.*, 1991); 2BBN (Ikura, M. *et al.*, 1992); 1IHJ (Kimple, M. E. *et al.*, 2001).

was implicated as the gene encoding rhodopsin in R1–6 (Rh1) since it affected the visual pigment concentration in a gene dosage-dependent manner (Scavarda, N. J. *et al.*, 1983). It was cloned and sequenced a couple of years after vertebrate rhodopsin (O'Tousa, J. E. *et al.*, 1985), itself the first member of the G-protein-coupled receptor (GPCR) family, with the now classical seven transmembrane helix structure (Figure 7). Rh1 (*ninaE*) shares ~36% identity with bovine rhodopsin, including the lysine in the seventh transmembrane helix, which forms the covalent Schiff base linkage with the chromophore, and potential phosphorylation sites near the C-terminal. Six further genes with a similar *nina* mutant ERG phenotype are involved either in rhodopsin trafficking (*ninaA, calnexin*) (Baker, E. K. *et al.*, 1994; Rosenbaum, E. E. *et al.*, 2006), or chromophore production (*ninaB*, *ninaD*, *ninaG*, and *pinta*, see below).

Table 1 List of mutants of genes involved in *Drosophila* phototransduction, all of which have been cloned and sequenced

Mutant	*Protein*	*Function*
Excitation		
Gαq	G_q α subunit	Heterotrimeric G protein
Gβe	G_q β subunit	Heterotrimeric G protein
InaD	PDZ domain scaffolding protein	Signalplex scaffold
inaF	Novel	Required for TRP function
ninaE	Rhodopsin (Rh1)	Visual pigment
norpA	Phospholipase Cβ	Key effector enzyme
trp	TRP channel	Light-sensitive channel
trpl	TRPL channel	Light-sensitive channel
Deactivation and adaptation		
arr1	39-kDa arrestin1	Rhodopsin endocytosis
arr2	49-kDa arrestin 2	Rhodopsin deactivation
cam	Calmodulin	Ca^{2+}-dependent inactivation and Ca^{2+} buffer
inaC	Protein kinase C	Ca^{2+}-dependent inactivation
ninaC	Class III myosin kinase	CaM binding, response inactivation
rdgA	DAG kinase	Response termination, PIP_2 recycling
Phosphoinositide turnover		
cds	CDP–DAG synthase	PIP_2 recycling
laza	Lipid phosphate phosphohydrolase	DAG production from PA
rdgB	PITP	PIP_2 recycling
Calcium homeostasis		
calnexin	Calnexin	Rh1 chaperone and Ca^{2+} buffer
calphotin	Ca^{2+}-binding protein	Ca^{2+} buffer
calx	Na^+/Ca^{2+} exchanger	Ca^{2+} extrusion
Rhodopsin and chromophore biogenesis and pigment cycle		
ninaA	Peptidyl-prolyl *cis–trans* isomerase (cyclophilin)	Rh1 chaperone
ninaB	Dioxygenase	Chromophore synthesis
ninaD	Class B scavenger receptor	Chromophore synthesis (carotenoid uptake)
ninaG	Oxidoreductase	Chromophore synthesis
pintA	Retinoid-binding protein	Vitamin A uptake into pigment cells
rdgC	Rhodopsin phosphatase	Rhodopsin dephosphorylation
GPRK1	Rhodopsin kinase	Rhodopsin phosphorylation

Mutant genes have been classified according to their major function – excitation, deactivation, PI turnover, Ca^{2+} homeostasis, and visual pigment cycle and biogenesis (not mutually exclusive, though each gene listed only once). References in text.

An additional five *Drosophila* opsin genes, identified by homology to Rh1, account for the visual pigments of the ocelli (Rh2) and the various spectral classes of R7 (Rh3 and Rh4), and R8 (Rh5 and Rh6) (Feiler, R. *et al.*, 1992; Salcedo, E. *et al.*, 1999).

More than 60 invertebrate opsin genes have been cloned in the meantime (reviewed in Gärtner, W., 2000), and although recognizable as such they form a distinct subfamily from the majority of vertebrate opsins. An intriguing exception is melanopsin (Provencio, I. *et al.*, 1998), which appears to belong within the invertebrate opsin family, but is a vertebrate opsin found in a recently discovered novel class of intrinsically photosensitive retinal ganglion cells (ipRGCs). Melanopsin mediates a range of nonvisual responses such as circadian entrainment and the pupillary response (reviewed in Fu, Y. *et al.*, 2005). The ipRGCs also respond to light by depolarization, and at least in heterologous expression systems, melanopsin has been found to activate a G_q/PLC/TRP cascade as in invertebrates (Melyan, Z. *et al.*, 2005; Panda, S. *et al.*, 2005; Qiu, X. *et al.*, 2005).

1.05.4.2.1 Chromophore

Unusually, the chromophore of *Drosophila* opsin, as in most Diptera and a few other insect orders, is not retinal but a hydroxylated derivative, 11-*cis* 3-hydroxy retinal (Figure 8; Vogt, K. and Kirschfeld, K., 1984). Whilst this appears to function in an essentially identical manner to the more conventional 11-*cis* retinal, Diptera are remarkable in also using a second chromophore, 3-hydroxy retinol, that functions as a sensitizing or antenna pigment (Kirschfeld, K. and Franceschini, N., 1977). The

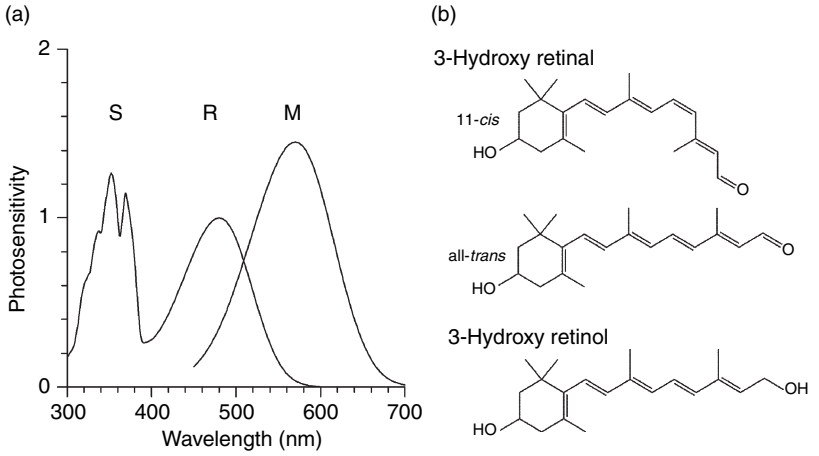

Figure 8 Chromophores and absorption spectra. Left: Idealized photosensitivity spectra of the Rh1 pigment system in *Drosophila* R1–6 cells, normalized to the rhodopsin (R) peak. Responses in the UV (300–400 nm) are primarily mediated by absorption of the sensitizing pigment (S: 3-hydroxy retinol), which transfers the energy of absorption to the chromophore proper (11-*cis* 3-hydryoxy retinal), which absorbs maximally at 480 nm in Rh1. Photoisomerization to all-*trans* 3-hydroxy retinal converts R to metarhodopsin (M), which absorbs maximally at 570 nm. The sensitizing pigment can also transfer energy to M, which is thus also effectively photoisomerized by UV light (not shown). Spectra based on rhodopsin nomograms (Govardovskii, V. I. *et al.*, 2000), combined with estimates of the sensitizing pigment spectrum. Right: Chemical structures of the chromophores of R and M (11-*cis* and all-*trans* 3-hydroxy retinal) and the sensitizing pigment (3-hydroxy retinol).

sensitizing pigment has a characteristic three-fingered absorption peak in the ultraviolet (peaks at ~330, 350, and 370 nm). It transfers the energy of an absorbed photon by fluorescence resonance energy transfer (FRET) to the chromophore proper, which then photoisomerizes exactly as if it had absorbed the photon directly (Kirschfeld, K. *et al.*, 1983). This rare biological example of FRET enhances quantum catch by extending the spectral sensitivity of the photoreceptors into the ultraviolet (Figure 8).

Recent biochemical and mutant analysis has identified several key genes required for chromophore production, including a class B scavenger receptor (*ninaD*), required for cellular uptake of dietary carotenoids (Kiefer, C. *et al.*, 2002), and a dioxygenase (*ninaB*), which cleaves the 40C carotenoids into the 20C chromophore precursor, vitamin A (all-*trans* retinol) (von Lintig, J. and Vogt, K., 2000; von Lintig, J. *et al.*, 2001). Whilst these stages take place outside the retina (Gu, G. *et al.*, 2004), uptake of vitamin A into the retina probably occurs first in the pigment cells, with the essential involvement of a recently identified retinal-binding protein, PINTA (Wang, T. and Montell, C., 2005). Finally, oxidization of the retinal ring to generate the hydroxylated 3-hydroxy retinal appears to take place in the photoreceptors via an oxidoreductase encoded by the recently discovered *ninaG* gene (Sarfare, S. *et al.*, 2005).

1.05.4.2.2 Invertebrate rhodopsins are bistable

Although *de novo* biosynthesis of chromophore from carotenoids is relatively complex, chromophore recycling following photoisomerization is much simpler than in vertebrates. Most invertebrate rhodopsins represent bistable, photointerconvertible pigment systems, whereby all-*trans* retinal can be directly reconverted to 11-*cis* by absorption of a second photon whilst still attached to the opsin. *Drosophila* Rh1, which has been extensively studied, absorbs maximally in the blue–green (480 nm), and on absorption of a photon, the 11-*cis* to all-*trans* isomerization leads to generation of a metarhodopsin (M) absorbing maximally at 570 nm (Figure 8). Metarhodopsin is thermostable, but can be photoisomerized back to the rhodopsin state (R) by absorption of a further photon. Such a bistable pigment system reaches a photoequilibrium determined by the spectral content of the illuminating light and the absorption spectra of the R and M states (reviewed in Hillman, P. *et al.*, 1983; Hardie, R. C., 1985; Stavenga, D. G., 1996). It is no coincidence that the screening pigments in the eye are transparent to long-wavelength (red) light – hence the red eye color

of most flies – and the red light diffusing through the eye reconverts M, ensuring that there is always a high fraction of R (reviewed in Hardie, R. C., 1986). Compared to the complex chromophore recycling of the vertebrate retina, this would appear to represent a much more efficient, rapid, and economical mechanism for pigment regeneration.

Under experimental conditions, however, particularly with white-eyed mutants lacking the screening pigments, or in biochemical preparations of purified photoreceptor membranes, it is possible to generate essentially any photoequilibrium simply by adjusting the wavelength of illumination. With blue light, which favors R → M conversion, up to ~80% of the pigment can be converted to the M form (it is not possible to create more than this as both R and M have second, overlapping photosensitivity peaks at short wavelengths due to β absorption peaks and sensitizing pigment). When flashes are delivered that result in more than ~20% of the pigment being converted to M, the photoreceptors develop a prolonged depolarizing afterpotential (PDA), that can last for several hours (Figure 5). This is because thermostable M remains active and capable of exciting the phototransduction cascade until it is inactivated by binding to arrestin (see Section 1.05.4.3.1). The photoreceptors contain only one arrestin molecule for every five rhodopsins, and thus, once more than 20% of the pigment exists in the M state, all arrestin is bound to M, and any further M molecules generated can no longer be inactivated. Although the PDA may last for several hours in *Drosophila*, it can be terminated at any time simply by delivering a bright long-wavelength (e.g., orange/red) flash, which inactivates M by reconverting it to R (Figures 5 and 9).

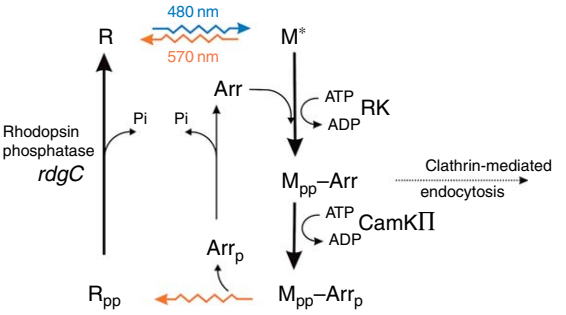

Figure 9 Visual pigment cycle in *Drosophila*. Photoisomerization of rhodopsin (R) by blue light (480 nm) generates active metarhodopsin (M^*). M^* is thermostable and continues to activate G_q until it binds arrestin (Arr). Arr2 is the dominant arrestin, but Arr1 can perform this function more slowly in its absence. M is also multiplely phosphorylated by rhodopsin kinase (RK), but this is not required for Arr2 binding and may even occur after Arr2 binding (Plangger, A. *et al.*, 1994). The M_{pp}–Arr state is a target for clathrin-mediated endocytosis, but this is inhibited by the CaMKII-dependent phosphorylation of Arr2 (Alloway, P. G. *et al.*, 2000; Kiselev, A. *et al.*, 2000b). Reconversion of M_{pp} to R_{pp} leads to the release of Arr_p. Finally, R_{pp} is dephosphorylated by the CaCaM-dependent rhodopsin phosphatase (encoded by *rdgC*) to recreate the ground state, R (Byk, T. *et al.*, 1993; Lee, S. J. and Montell, C., 2001).

1.05.4.3 Visual Pigment Cycle

1.05.4.3.1 Arrestins terminate active metarhodopsin

Arrestins are small soluble cytosolic proteins implicated in response termination and trafficking of most G-protein-coupled receptors. *Drosophila* photoreceptors express two arrestin isoforms: a 39 kDa protein (Arr1, originally called phosrestin 2) and 49 kDa Arr2 (or phosrestin 1). Arr2 is approximately fivefold more abundantly expressed than Arr1, and apart from Rh1 is the most abundant protein in the retina. As such, it was the only element of the cascade to be sequenced by protein purification and microsequencing (Yamada, T. *et al.*, 1990), whilst Arr1 was cloned by a subtractive hybridization strategy (Hyde, D. R. *et al.*, 1990). Both share ~40% identity with human arrestin, showing closer similarity to β-arrestins than the vertebrate visual arrestins (Figure 7). Mutants of both *arr1* and *arr2* genes were isolated by screening for loss of protein in Western blots (Dolph, P. J. *et al.*, 1993). As expected from its abundance, Arr2 is dominant with respect to inactivation of M. Thus *arr1* mutants have no overt physiological phenotype, though they undergo light-independent degeneration (Satoh, A. K. and Ready, D. F., 2005). By contrast, *arr2* mutants have a pronounced deactivation defect, with responses to brief flashes decaying slowly over 1–2 s (Figure 10). *arr2* mutants also enter a PDA state with much lower levels of illumination (Dolph, P. J. *et al.*, 1993). Although these phenotypes indicate that Arr2 binding to M is the dominant mechanism of M inactivation, Arr1 is also capable of binding to and inactivating M, since response deactivation in *arr1*;*arr2* double mutants lacking both arrestin isoforms is at least 10× slower than in *arr2* alone (Dolph, P. J. *et al.*, 1993). A recent study indicates that Arr1 also has a dedicated role in light-induced Rh1 endocytosis, a generic mechanism of receptor turnover found in most G-protein-coupled signaling cascades required for receptor turnover and cell maintenance (Satoh, A. K. and Ready, D. F., 2005).

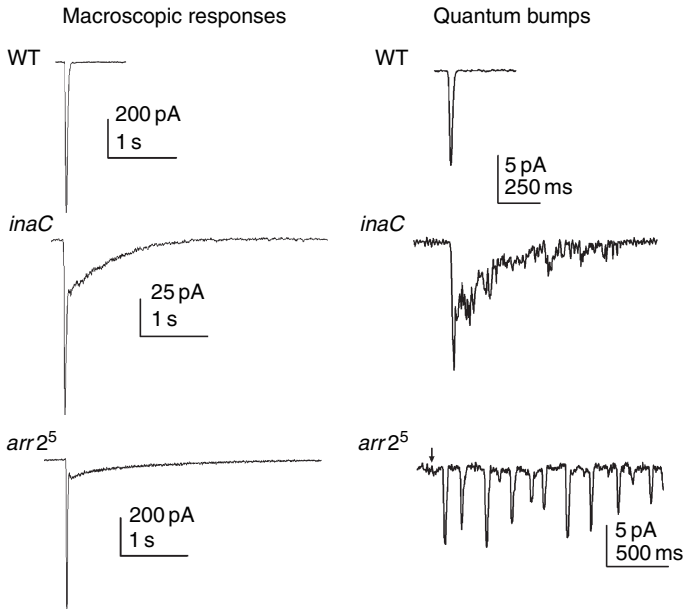

Figure 10 Responses in inactivation mutants. Left: Whole-cell voltage-clamped responses to brief (1 ms) flashes of light in wild type (WT) and two mutants (*inaC* and *arr2*^{5}) with defects in inactivation. Right: Quantum bumps elicited by single-photon absorptions in the same mutants. Macroscopically, both *inaC* and *arr2* mutants show a similar inactivation defect, with responses decaying over a period of 1–2 s. In the PKC mutant *inaC*, this defect is recapitulated in the bump waveform, and is due to a defect late in the transduction cascade (failure to inactivate PLC and the channels); however, in the arrestin 2 mutant (*arr2*^{5}) the defect manifests itself as a train of multiple bumps in response to a single absorbed photon, and represents a failure to terminate the activity of active metarhodopsin (Hardie, R. C., unpublished data; see also Hardie, R. C. *et al.*, 1993; Scott, K. *et al.*, 1997; Gu, Y. *et al.*, 2005).

1.05.4.3.2 Arrestin translocation

Light-induced translocation of components of the transduction cascade in both vertebrates and invertebrates has recently been appreciated as an important and widespread phenomenon, likely to be involved in long-term light and dark adaptation (reviewed in: Arshavsky, V. Y., 2003; Frechter, S. and Minke, B., 2006). In *Drosophila*, both arrestins, along with the G protein and the TRPL channel, have been reported to translocate in response to illumination. In DA cells most Arr2 is distributed throughout the cytosol, with only ~30% immunolocalized in the rhabdomeres, whilst Arr1 is only detectable in the cytosol; however, within 5 min of illumination by white or blue light, both Arr2 and Arr1 are predominantly localized in the rhabdomere (Lee, S. J. *et al.*, 2003; Satoh, A. K. and Ready, D. F., 2005). Arr2 remains in the rhabdomere during illumination, returning slowly (within 3 h) to the cytosol in the dark (Figure 11). The translocation of Arr2 into the rhabdomeres appears to have physiological consequences, as the ERG response to bright stimuli terminated more quickly in flies that had been preexposed to light to stimulate translocation (Lee, S. J. *et al.*, 2003). Arr1 translocation is more dynamic and transient, and even in continuous illumination Arr1 retreats from the rhabdomere within 30 min and is then found internalized in vesicles in association with Rh1 (Figure 11), indicative of a role in physiological Rh1 endocytosis (Satoh, A. K. and Ready, D. F., 2005).

Lee S. J. *et al.* (2003) found that Arr2 binds to PIP_3 *in vitro* (and less avidly to PIP_2), and that translocation was disrupted by neutralization of three basic residues in Arr2 required for this interaction (lysines 228, 231, and 257), or by genetic manipulation of PIP_3 metabolism. Lee S. J. and Montell C. (2004) also reported that translocation was disrupted in *ninaC* mutants (see Section 1.05.4.9) and proposed a model whereby Arr2 is transported by a NINAC myosin motor in PIP_3-enriched vesicles. However, a more recent study found that translocation of both Arr1 and Arr2 was unaffected by the *ninaC* mutation calling aspects of this model into question (Satoh, A. K. and Ready, D. F., 2005).

1.05.4.3.3 Rhodopsin kinase and phosphatase

In vertebrate rods, metarhodopsin inactivation is a two-stage process, whereby M must first be

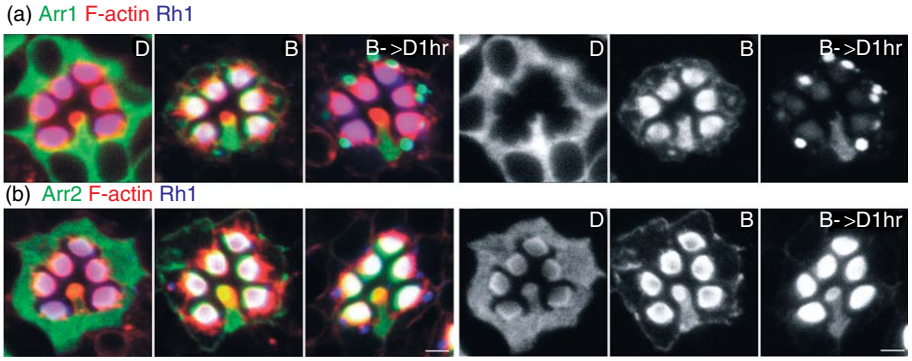

Figure 11 Translocation of arrestin. Immunostaining of Arr1 and Arr2 (green) in dark-adapted (D) retina, 5 min after illumination for 2 min by bright blue light (B), and 1 h after the same blue illumination (B > D 1 h). Sections are also stained for Rh1 (blue) and actin (red). The black and white image shows just the arrestin antibody staining. In the dark, all Arr1 is localized in the cytosol, whilst Arr2 is found in both cytosol and rhabdomere. Five minutes after illumination, both arrestins are found almost exclusively in the rhabdomeres. One hour later in the dark, Arr2 remains bound in the rhabdomeres, but Arr1 is now found predominantly in vesicles in the cell body, which also stain positive for Rh1. Images courtesy of Akiko Satoh and Don Ready (unpublished); see also Satoh A. K. and Ready D. F. (2005) for further details.

phosphorylated by a rhodopsin kinase (RK) before arrestin can bind and complete the inactivation (see Phototransduction in Rods and Cones). Unexpectedly, although fly rhodopsin is also multiplely phosphorylated at several serine residues in the C-terminal (Bentrop, J. and Paulsen, R., 1986; Byk, T. *et al.*, 1993), this appears not to be required for arrestin binding (Figure 9). Thus, transgenic flies in which the rhodopsin is replaced by a truncated version lacking the serine residues (*ninaE*$^{\Delta 356}$), or by a construct in which the serines have been individually mutated to alanine, show responses apparently normal in every respect including bump amplitude and waveform (Hardie, R. C., unpublished) and response inactivation (Vinos, J. *et al.*, 1997). The mutant Rh1 constructs also still bind Arr2 in biochemical assays (Kiselev, A. *et al.*, 2000a). Recently, Satoh A. K. and Ready D. F. (2005) reported that translocation of Arr1 and subsequent endocytosis of Arr1–Rh1 complexes was suppressed in these Rh1 phosphorylation mutants, suggesting that Rh1 phosphorylation may be specifically important for Rh1 binding to Arr1 (and/or its subsequent endocytosis) rather than Arr2.

A *Drosophila* G-protein-coupled receptor kinase (GPRK1) with homology to β-adrenergic receptor kinases has recently emerged as a strong candidate for RK. It is highly expressed in the photoreceptors where it associates with and phosphorylates rhodopsin (Lee, S. J. *et al.*, 2004). Interestingly, mutant flies expressing lower levels of GPRK1 had a significantly larger ERG responses, but without obvious response termination defects. Although responses were not measured at the single-cell level, at first sight this seems inconsistent with the lack of effect of the Rh1 phosphorylation site mutants on the response, which indicates that GPRK1 may also have a protein kinase-independent function.

After photoreisomerization from M to R, Arr2 is released from R, which must then be dephosphorylated before it can be used again (Figure 9). Dephosphorylation, which only takes place after Arr2 has been released, is mediated by a Ca^{2+} calmodulin (CaCaM)-dependent rhodopsin phosphatase encoded by the retinal degeneration C (*rdgC*) gene (Steele, F. R. *et al.*, 1992; Byk, T. *et al.*, 1993; Vinos, J. *et al.*, 1997; Lee, S. J. and Montell, C., 2001). *rdgC* mutants have a slow deactivation phenotype, but this may reflect a secondary defect, e.g., in Arr2 function, and is unlikely to be an immediate and direct consequence of the failure to dephosphorylate R, since by this stage in the rhodopsin cycle, the active M form should already have been inactivated by arrestin binding (Vinos, J. *et al.*, 1997). The original and most obvious phenotype of *rdgC* mutants, namely the severe light-dependent retinal degeneration, is suppressed by the truncated Rh1 phosphorylation site mutant *ninaE*$^{\Delta 356}$, and also by *arr2* mutations, suggesting that the accumulation of hyperphosphorylated M–Arr2 complexes may act as a trigger for apoptosis (Vinos, J. *et al.*, 1997; Kiselev, A. *et al.*, 2000a).

1.05.4.3.4 Arrestin phosphorylation

Both arrestin isoforms are themselves also phosphorylated in a light-dependent manner, and in fact Arr2 is

the major phosphoprotein revealed in proteomic analysis (Matsumoto, H. and Pak, W. L., 1984). It is also the most rapidly detectable phosphorylated protein in the eye, being phosphorylated by calmodulin-dependent kinase II (CaMKII) at a single serine residue (Ser^{366}) on a subsecond timescale following illumination (Matsumoto, H. and Pak, W. L., 1984; Matsumoto, H. *et al.*, 1994). Although it was originally speculated that CaMKII-dependent phosphorylation of Arr2 may be a necessary first step in the binding of arrestin to M, this seems not to be the case. Arr2 phosphorylation is prevented by mutating Ser^{366} to alanine ($Arr2^{S366A}$) or in the $arr2^{1}$ allele, in which the protein is truncated prior to this site (Alloway, P. G. and Dolph, P. J., 1999). However, Arr2 still binds normally to M in either of these mutants. The defect appears rather to be in the subsequent dissociation of Arr2 from rhodopsin after reconversion to R (Figure 9). Thus normally, Arr2 dissociates rapidly from M after it has been reconverted to R by long-wavelength light, but remains bound in $Arr2^{S366A}$ or $arr2^{1}$ (Alloway, P. G. and Dolph, P. J., 1999). Related to this, the phosphorylation also controls the subsequent trafficking of M–Arr2 complex, which become internalized by clathrin-mediated endocytosis if Arr2 fails to be phosphorylated (Kiselev, A. *et al.*, 2000a). This has the consequence that following light exposure, the non-phosphorylated mutant Arr2 becomes sequestered in stable complexes with phosphorylated rhodopsin, again triggering apoptosis and retinal degeneration. Before the onset of degeneration, it also results in a deactivation phenotype similar to an *arr2* hypomorph, presumably because there is no longer sufficient free Arr2 to inactivate M (Alloway, P. G. and Dolph, P. J., 1999; Alloway, P. G. *et al.*, 2000; Kiselev, A. *et al.*, 2000a).

In summary, it appears that, whilst having no direct role in the electrophysiological response, the rhodopsin and arrestin phosphorylation and dephosphorylation cycles (Figure 9) play vital, though still incompletely understood roles in rhodopsin turnover and photoreceptor maintenance and survival. Thus, as described above, *rdgC* mutants undergo light-dependent degeneration because of the accumulation of hyperphosphorylated metarhodopsin bound to arrestin. Since the *rdgC* rhodopsin phosphatase is dependent on the Ca^{2+} influx associated with the light response, hyperphosphorylated rhodopsin also accumulates in any mutants of the transduction cascade that block transduction, such as *norpA* (see below), and these mutants probably degenerate by a similar mechanism (Byk, T. *et al.*, 1993; Alloway, P. G. *et al.*, 2000; Kiselev, A. *et al.*, 2000a). Alloway P. G. *et al.* (2000) speculate that the clathrin-mediated endocytosis of M–Arr2 complexes may be a mechanism for removal of defective rhodopsin molecules, whilst Satoh A. K. and Ready D. F. (2005) suggest that Arr1 may play a scavenging role, binding phosphorylated M before it can accumulate in the lethal Arr2–M-p complexes. In support of this, they found that the light-independent degeneration in *arr1* mutants is actually rescued in the *arr1*;*arr2* double mutant.

1.05.4.4 Heterotrimeric G Protein

Heterotrimeric G proteins are holoenzymes composed of α, β, and γ subunits, with the α subunit bound to GDP in the (heterotrimeric) resting state (Figure 7). In common with all such G proteins, the G protein in the *Drosophila* phototransduction cascade is activated by interaction with the active receptor (M), which catalyzes the exchange of GDP for GTP on the α subunit, resulting in release of the active GTP-bound α subunit (Figure 6). The α subunit binds and activates its effector enzyme (in this case PLC), which then remains active until the GTP is hydrolyzed to GDP promoting dissociation of $G_q\alpha$ from PLC and its reassociation with $G\beta\gamma$.

Curiously, no mutants of any of the three G protein subunits were isolated in the early mutagenesis screens, but a strong candidate gene for the α subunit was identified amongst a collection of retinal genes identified by subtractive hybridization (Lee, Y. J. *et al.*, 1990). This G protein showed ~75% identity to mouse $G_q\alpha$, the isoform known to specifically couple to PLC. A role in transduction was indicated by showing it was localized in the rhabdomeres and by overexpressing a constitutively active form in the retina, which resulted in constitutive GTPase activity in the eye and suppression of the light response (Lee, Y. J. *et al.*, 1994). Definitive confirmation came with the characterization of a severe hypomorphic mutant *Gαq*, again isolated by screening for antigenicity, in which protein levels were reduced to <1%. Sensitivity to light in these mutants was reduced ~1000-fold (Figure 12), but this could be rescued in a dose-dependent manner by $G_q\alpha$ cDNA expressed under control of a heat-shock promoter (Scott, K. *et al.*, 1995).

The responses of *Gαq* mutants also appear to have a slow response deactivation (Figure 12); however, analysis of the underlying quantum bumps indicated, that this actually represents generation of bumps with delayed latencies, thereby substantially broadening the latency distribution. This can be readily

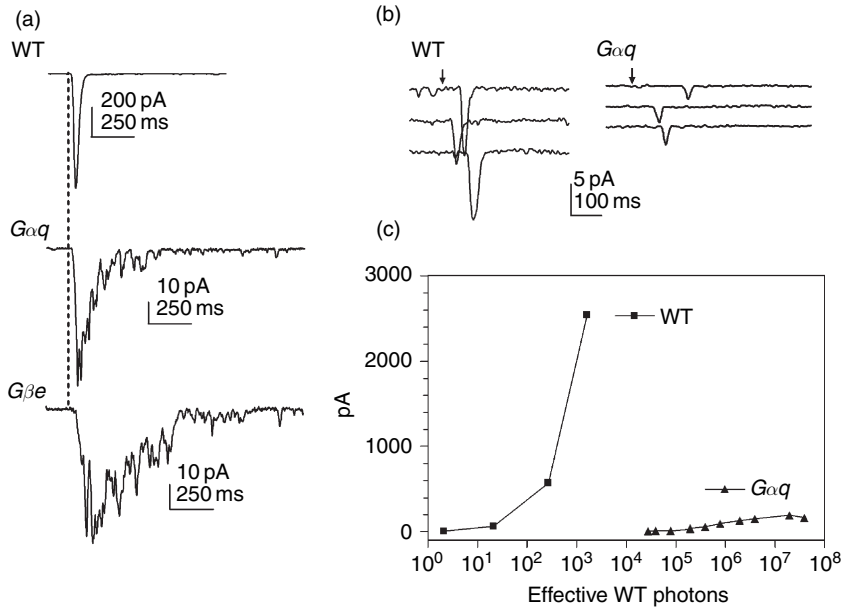

Figure 12 Responses in mutants of G_q. (a) Whole-cell voltage-clamped responses to brief (1 ms) flashes of light in wild type (WT), and in *Gαq* and *Gβe* mutants: (intensity for *Gαq* ~1000 times, and for Gβe ~100 times greater than for WT). Apart from the greatly reduced sensitivity, responses in both *Gαq* and *Gβe* show slow kinetics. For *Gαq* this is explained by delayed activation leading to longer bump latency (Scott, K. *et al.*, 1995), but in *Gβe* an additional defect in deactivation has been proposed (Dolph, P. J. *et al.*, 1994). (b) Individual quantum bumps elicited by dim flashes in *Gαq* are ~5× smaller than in WT. (c) Response intensity functions for WT and *Gαq* mutants: intensity expressed in effectively absorbed photons in WT photoreceptors. Adapted with permission from Hardie, R. C., Martin, F., Cochrane, G. W., Juusola, M., Georgiev, P., and Raghu, P. 2002. Molecular basis of amplification in *Drosophila* phototransduction. Roles for G protein, phospholipase C, and diacylglycerol Kinase. Neuron 36, 689–701; see also Dolph P. J. *et al.* (1994); Scott K. *et al.* (1995); Hardie R. C. *et al.* (2002).

understood by considering that one of the determinants of latency is the time taken for G protein to encounter the active M by diffusion in the microvillar membrane (see Section 1.05.8.2). Clearly, if the number of G proteins per microvillus is greatly reduced, then it will take longer on average for a G protein to encounter the single activated M in the microvillus (Scott, K. *et al.*, 1995).

Quantum bump amplitudes in *Gαq* (Scott, K. *et al.*, 1995), and also in hypomorphic PLC (*norpA*) mutants (Deland, M. C. and Pak, W. L., 1973; Cook, B. *et al.*, 2000), were originally reported to be the same as in WT, leading to the concept that amplification of the quantum bump was determined entirely downstream of PLC – that is, PLC activation serves only as a trigger for the quantum bump. However, it was subsequently found that quantum bumps were reduced by approximately fivefold in both these mutant backgrounds, indicating that G_q and PLC also contribute to the amplification process, and that normally activation of several G protein and PLC molecules is required to generate a full size quantum bump (Figures 12 and 13, Hardie, R. C. *et al.*, 2002). The discrepancy was attributed to the omission of ATP from the patch electrodes solution in earlier studies, resulting in artefactual amplification of the small bumps, probably as a consequence of reduced DAG kinase activity (Hardie, R. C. *et al.*, 2002) (see also Figure 16 and Section 1.05.5.1).

1.05.4.4.1 G protein β and γ subunits

A G protein β subunit that is expressed predominantly in the rhabdomeres has also been identified (Yarfitz, S. *et al.*, 1991; Yarfitz, S. L. *et al.*, 1994). Mutants (*Gβe*), subsequently isolated by screening for antigenicity, also show a greatly (~100-fold) decreased sensitivity to light (Dolph, P. J. *et al.*, 1994) as well as reduced light-induced GTPγS binding to retinae of cryosectioned heads (Yarfitz, S. L. *et al.*, 1994). Although this may indicate that Gβ is essential for effective coupling of $G_q\alpha$ with M, a recent study found that the majority of $G_q\alpha$ was mislocalized to the cytosol in *Gβe* mutants, i.e., the reduced sensitivity could in principle also be explained as consequence of G protein and rhodopsin being in separate cellular compartments (Elia, N. *et al.*, 2005). Interestingly, *Gβe* mutants also show a distinct

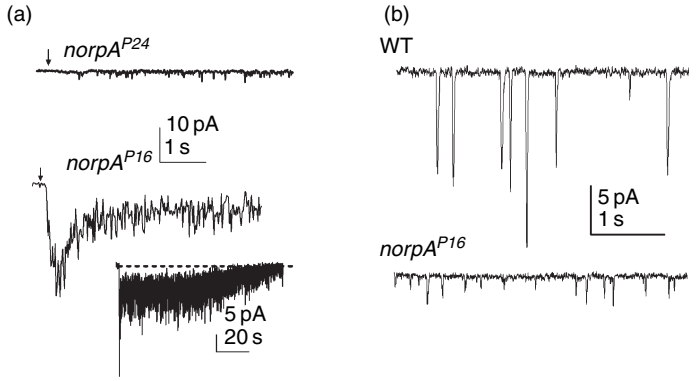

Figure 13 *norpA* mutant responses. (a) Whole-cell voltage-clamped responses to brief flashes of light (containing ~10^5 effectively absorbed photons) in the null PLC mutant *norpA*^{P24} and the severe hypomorph *norpA*^{P16}. Even in the supposedly null *norpA*^{P24}, a few ~1 pA bumps are elicited in response to bright illumination, whilst the same intensity elicits a small response in *norpA*^{P16} (these intensities would generate saturating responses in wild-type (WT) flies). Inset, on a slower timescale shows that the response in *norpA*^{P16} lasts for several minutes. (b) Quantum bumps in *norpA*^{P16} (recorded in the tail of a response to a weaker flash), are greatly reduced compared to WT (above). Adapted with permission from Hardie, R. C., Martin, F., Cochrane, G. W., Juusola, M., Georgiev, P., and Raghu, P. 2002. Molecular basis of amplification in *Drosophila* phototransduction. Roles for G protein, phospholipase C, and diacylglycerol Kinase. Neuron 36, 689–701.

deactivation defect, which is more severe than in $G\alpha q$ mutants (Figure 12), suggesting a distinct role for $G\beta$ in response termination (Dolph, P. J. *et al.*, 1994). There are no null or hypomorphic mutants of the G protein γ subunit; however, a dominant negative construct lacking the farnesylation site require for membrane anchoring also reduces light sensitivity as measured by ERG, presumably by sequestering $G\beta$ subunits away from the membrane (Schillo, S. *et al.*, 2004).

1.05.4.4.2 G_q translocation

Along with the arrestins (Section 1.05.4.3.2) and the TRPL channels (transient receptor potential-like translocation), G_q is one of three components of the *Drosophila* cascade that has been shown to translocate in response to illumination. In the dark, the majority of the G protein is found concentrated in the microvilli. However, following saturating illumination with blue light, ~50% of the $G_q\alpha$ is released from the membrane and moves out into the cell body over a time course of 50 min, returning to the rhabdomere slightly more slowly in the dark (Kosloff, M. *et al.*, 2003). Translocation was little affected by mutations in PLC, though curiously was largely blocked in mutants of the TRP channel. Like other G proteins, G_q is not a transmembrane protein, but can be anchored to the membrane by reversible palmitoylation of the α subunit, suggesting that depalmitoylation may be required to initiate the translocation (Kosloff, M. *et al.*, 2003). The return of $G_q\alpha$ in the dark was blocked in $G\beta e$ mutants, indicating that targeting to the microvillar membrane also requires $G\beta$ or, more likely, $G\beta\gamma$ with involvement of the farnesylation of the γ subunit in membrane anchoring.

1.05.4.5 Phospholipase C (NORPA)

Severe mutants of the *n*o *r*eceptor *p*otential *A* (*norpA*) gene have effectively no response to light, and were isolated independently by both the Pak and the Benzer groups (Hotta, Y. and Benzer, S., 1970; Pak, W. L. *et al.*, 1970). Although evidence had already implicated the PI cascade in invertebrate phototransduction (Brown, J. *et al.*, 1984; Fein, A. *et al.*, 1984; Inoue, H. *et al.*, 1985; Devary, O. *et al.*, 1987), the finding that *norpA* encoded a PI-specific PLC (Bloomquist, B. T. *et al.*, 1988) provided clear genetic evidence that PLC was the effector enzyme of the phototransduction cascade in *Drosophila* and represented a key milestone in the analysis of invertebrate phototransduction. Appropriate for its role, the NORPA protein was found to be highly enriched in the eyes and immunogold labeling showed it to be specifically localized to the rhabdomeres (Schneuwly, S. *et al.*, 1991). Although the obligatory control demonstrating that *norpA* cDNA could genetically rescue the mutant phenotype was not performed until much later (McKay, R. R. *et al.*, 1995); importantly, possible pleiotropic developmental effects of this mutation had already been effectively excluded by the availability of temperature-sensitive

alleles of *norpA* in which the light response was rapidly and reversibly abolished by warming to 35 °C (Deland, M. C. and Pak, W. L., 1973).

NORPA, one of the first PI-specific PLCs to be cloned, is clearly recognizable as a PLCβ isoform, which unlike PLCγ and PLCδ, are activated by interaction with heterotrimeric G proteins. Thus, NORPA has up to 60% identity with mammalian PLCβs in the conserved X and Y domains, which form the catalytic core of the enzyme and contains a C2 domain that may be involved in Ca^{2+}-dependent targeting to the membrane (reviewed in Pak, W. L., 1995). Interestingly, one of the vertebrate PLCβ isoforms (PLCβ4) is more closely related to NORPA than any other vertebrate PLC isoform and is predominantly expressed in the vertebrate cones (Ferreira, P. A. and Pak, W. L., 1994). Its role in vertebrate photoreceptors is not known, but may hint at some distant evolutionary common ancestral photoreceptor.

1.05.4.5.1 Phospholipase C is also a GTPase-activating protein

Numerous mutant alleles of the *norpA* gene have been isolated, which vary widely in their severity (Pearn, M. T. *et al.*, 1996). The most severe, such as $norpA^{P24}$, which has a 28-bp deletion resulting in a frameshift and a premature stop codon, have essentially no response to even saturating flashes (but see Figure 13 and Hardie, R. C. *et al.*, 2003) and no detectable protein. However, others such as $norpA^{P57}$ and $norpA^{P16}$ have residual protein and substantial responses to bright illumination. As well as a marked reduction in sensitivity, such hypomorphic alleles also have dramatically prolonged responses to light that can persist for many minutes, the time course increasing with the severity of the mutation (Figure 13, Scott, K. and Zuker, C. S., 1998; Cook, B. *et al.*, 2000). A combined electrophysiological and biochemical study indicated that this reflects the requirement for PLC to act as a GTPase-activating protein (GAP), essential to terminate the activity of $G_q\alpha$ subunit (Cook, B. *et al.*, 2000). With severely reduced PLC levels, it appears that $G_q\alpha$ subunits remain active indefinitely (for many minutes), before finally encountering and binding to a PLC molecule, only then initiating a cycle of bump generation, PLC inactivation, and response termination. GAP activity of the effector enzyme is a common feature in G protein signaling and as in vertebrate rods, such a mechanism is important in ensuring the fidelity of the response to light. Thus, firstly the G protein stays active until it has had the chance to activate its target (PLC), but then it is rapidly inactivated ensuring that only one bump is generated. Whether or not RGS proteins are also involved as GAP proteins, as in vertebrate photoreceptors, is not known.

1.05.4.5.2 Measuring phospholipase C activity

Light- and *norpA*-dependent PLC activity, generating DAG and $InsP_3$ from PIP_2 has directly been demonstrated in biochemical assays, using radiolabeled inositol or PIP_2 (Inoue, H. *et al.*, 1985; Devary, O. *et al.*, 1987; Toyoshima, S. *et al.*, 1990; Running Deer, J. L. *et al.*, 1995). Like other PLCs, *Drosophila* NORPA shows *in vitro* dependence on Ca^{2+}, both basal and light-activated PLC activity being increased in the range from 10 nm to 1 μM, and inhibited in the high micromolar range (Toyoshima, S. *et al.*, 1990; Running Deer, J. L. *et al.*, 1995).

The only available quantitative biochemical measurements come from squid, indicating that ~500 PIP_2 molecules can be hydrolyzed per absorbed photon (Szuts, E. Z., 1993). However, semiquantitative *in vivo* estimates of PIP_2 hydrolysis rates in *Drosophila* have recently been made using biosensors in the guise of PIP_2-sensitive inward rectifier ion channels (Kir2.1), genetically targeted to the rhabdomeres (Hardie, R. C. *et al.*, 2001; 2004). These channels are activated by PIP_2, and their open probability is simply related to PIP_2 concentration. When they replace the light-sensitive channels, they generate a constitutively active inward current maintained by the endogenous resting PIP_2 levels. This current is suppressed in an intensity-dependent manner by illumination, providing a rather direct *in vivo* measure of PIP_2 hydrolysis. The suppression of the Kir2.1 current by light indicated that PLC activity corresponded to rates of ~150% of the PIP_2 in the microvillus per second per effectively absorbed photon (Figure 14, Hardie, R. C. *et al.*, 2004). Interestingly, in complete darkness, a remarkably high basal PLC activity could also be readily resolved after blocking PIP_2 synthesis by ATP deprivation. Although ~1000× less than maximum light-induced rates, this was still sufficient to effectively deplete the rhabdomere of PIP_2 within 5–10 min (Figure 14).

Kir2.1 biosensors, in combination with manipulation of cytosolic Ca^{2+}, also allowed *in vivo* measurements of the Ca^{2+} dependence of basal and light-induced PLC activity. Broadly, these confirmed

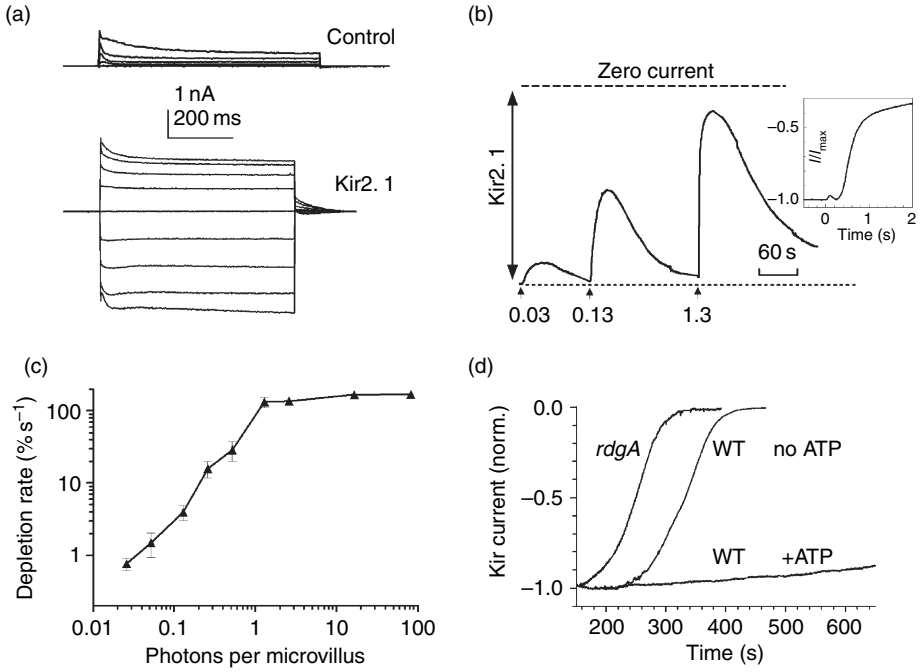

Figure 14 PIP_2 hydrolysis monitored with PIP_2 biosensor channels Kir2.1. Whole-cell recordings of inward K^+ currents in photoreceptors expressing the PIP_2-sensitive inwardly rectifying Kir2.1 channel. (a) Voltage steps (from −100 to −20 mV in 10 mV steps). In control cells, only outward K currents (mainly *Shaker* and *Shab*) are activated, but in cells expressing Kir2.1 large inwardly rectifying currents are seen at negative potentials. (b) When expressed in photoreceptors of *trpl*;*trp* double mutants, Kir2.1 is the only light-sensitive conductance in the cell. In the dark a large, ~1 nA constitutive current is activated by the prevailing PIP_2 levels (extent indicated by double arrow). Calibrated stimuli (0.03 etc., expressed in effectively absorbed photons per microvillus) suppress the current due to hydrolysis of PIP_2 by PLC: flashes containing one photon per microvillus deplete the entire rhabdomere of the majority of detectable PIP_2 within ~1 s (inset shows a response on a faster timescale). The Kir2.1 current is reactivated with a half time of ~60 s in the dark, representing the resynthesis of PIP_2. (c) Intensity response function of PLC activity – measured from the maximum slope of individual flash responses as in (b). Note that there is no Ca^{2+} influx associated with the light response in these experiments: under normal conditions, Ca^{2+} influx via TRP channels rapidly inhibits PLC activity, so that these rates of PLC activity will only be reached and briefly sustained during the latent period of the quantum bump (see Section 1.05.6.2). (d) Basal PLC activity monitored *in vivo* as a function of time after establishing the whole-cell configuration: a control (wild type (WT)) cell held in the dark with ATP in the patch pipette shows only very gradual rundown of the Kir2.1 current over 10 min. Without ATP however, the current decays to near zero within ~6 min. A similar behavior is seen in the *rdgA* mutant demonstrating ongoing basal PLC activity in this mutant as well. Adapted from Hardie, R. C., Gu, Y., Martin, F., Sweeney, S. T., and Raghu, P. 2004. *In vivo* light-induced and basal phospholipase C activity in *Drosophila* photoreceptors measured with genetically targeted phosphatidylinositol 4,5-bisphosphatesensitive ion channels (Kir2.1). J. Biol. Chem. 279, 47773–47782.

in vitro measurements; however, facilitation by Ca^{2+} was only noted in the range ~10–100 nM, and maximal activity appeared already to be reached at physiological resting levels of Ca^{2+} (Hardie, R. C., 2005). As discussed later (see Section 1.05.6.1.1), much higher concentrations (>50 μM) strongly inhibited PLC activity *in vivo*.

1.05.4.6 Light-Sensitive Channels *trp* and *trpl*

The *Drosophila* transient receptor potential mutant, *trp*, was first isolated as a spontaneously occurring mutation, in which the photoreceptor's response to light decayed to baseline during prolonged illumination (Cosens, D. J. and Manning, A., 1969; Minke, B. *et al.*, 1975). After the gene was positionally cloned (Montell, C. and Rubin, G. M., 1989), it was found to encode a novel transmembrane protein. Since mutants still had a light response, it was originally considered unlikely that TRP represented the light-sensitive channel. However, Hardie R. C. and Minke B. (1992) demonstrated that the Ca^{2+} selectivity of the light-sensitive current was reduced tenfold in *trp* mutants, leading to the proposal that it represented the major, Ca^{2+} selective component of

the light-sensitive current, and that a second, less Ca^{2+} permeable channel was responsible for the residual response in the *trp* mutant. At the same time, Phillips A. M. *et al.* (1992) reported the sequence of a second channel-like gene (TRP-like, or TRPL), now known to be responsible for this residual response (Niemeyer, B. A. *et al.*, 1996; Reuss, H. *et al.*, 1997). Both TRP and TRPL have been shown to be predominantly localized in the microvilli by immunogold labeling (Niemeyer, B. A. *et al.*, 1996), although as detailed below (see Section 1.05.4.6.4), TRPL may also be found in the cell body following translocation.

1.05.4.6.1 Structure of TRP and TRPL

The TRPL protein shares 40% identity to TRP and both sequences show structural similarity with the voltage-gated Ca^{2+} channel family with six transmembrane (TM) helices and a pore loop (Phillips, A. M. *et al.*, 1992). Unlike Ca^{2+} channel genes, which encode four such 6TM domains in a single peptide, the *trp* and *trpl* genes encode only one such domain, and consequently, like voltage-gated K channels or CNG channels, TRP channels are believed to be composed of homo- or heterotetramers. The identification of TRP as a PLC-regulated cation channel heralded the discovery of some 30 vertebrate isoforms, divided into seven subfamilies (TRPC, TRPV, TRPM, TRPML, TRPP, TRPA, and TRPN). They have remarkably diverse functions throughout the body, most notably, but by no means exclusively, in sensory transduction (reviewed in: Clapham, D. E., 2003; Montell, C., 2005; Ramsey, I. S. *et al.*, 2006).

Drosophila TRP and TRPL share closest homology with the vertebrate TRPC (*c*anonical TRP) subfamily, with similar overall topology, including four N-terminal ankyrin repeats (protein binding motifs) and a coiled-coil (CC) region in the N-terminal, and six transmembrane segments with a pore loop between S5 and S6 (Figure 15). The most highly conserved region is the so-called TRP domain, which is immediately adjacent to S6. In vertebrate TRPC1, part of this domain can serve as a binding site for a

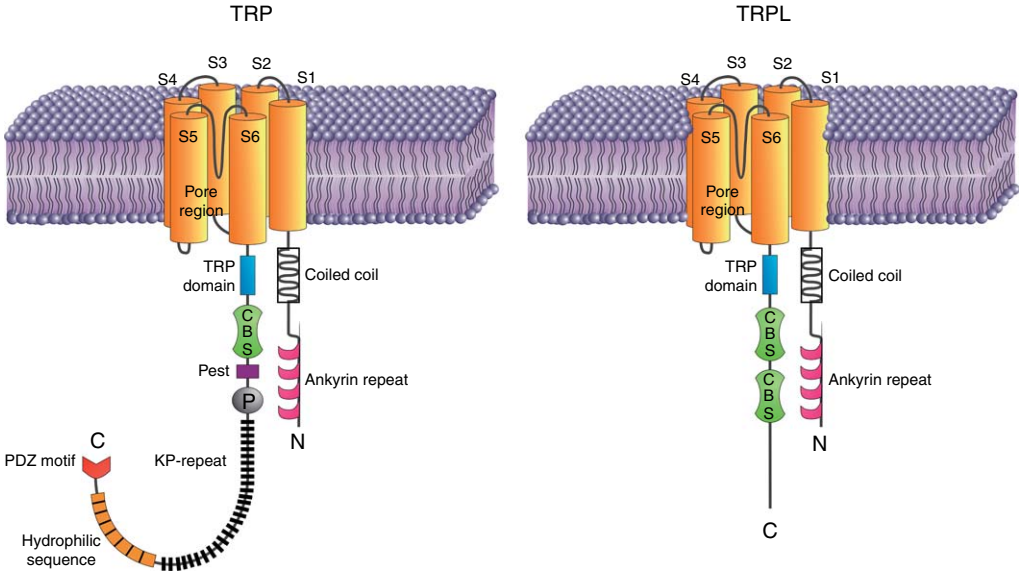

Figure 15 Structural features of the TRP and TRPL channel subunits. TRP and TRPL both belong to the overall superfamily of voltage-gated Ca^{2+}/Na^{+} and K^{+} channels and CNG channels; and represent subunits of tetrameric channels. Each subunit has six transmembrane helices (S1–S6), with a pore helix and pore loop between S5 and S6. The S4 helix lacks the positively charged residues characteristic of the voltage-gated members of the family. Their N-termini contain a coiled-coil region (CC) and four ankyrin repeats, which are potential protein–protein interaction domains. The most highly conserved region is the TRP domain adjacent to S6, with the motif EWKFAR found in all TRPC channels, and which is still recognizable in other TRP subfamilies. TRP has one, and TRPL, two CaM-binding sites (CBS) in the C-termini. TRP has an extended C-terminus with a PEST sequence, a proline-rich region with 29 KP repeats, multiple repeats of a hydrophilic eight to nine peptide sequence DKDKKP(A/G)D, and a PDZ domain binding motif in the last three amino acids required for binding to the INAD protein. Ser^{982} has been implicated as an *in vivo* PKC phosphorylation site (P) required for effective response termination (Popescu, D. C. *et al.*, 2006).

scaffolding protein, Homer, which is proposed to mediate interaction with $InsP_3$ receptor ($InsP_3R$) (Yuan, J. P. *et al.*, 2003). However, given that TRP channels are activated normally in the $InsP_3R$ null mutants in the photoreceptors (Section 1.05.5.1), the significance of this region in the *Drosophila* TRPs is not known. The rest of the C-terminal is rather divergent – both between TRP and TRPL and the vertebrate TRPCs – though all include one or more consensus CaM-binding domains (see Section 1.05.6.2.1). TRP has a conspicuously long C-terminal domain containing a proline-rich region, eight to nine peptide repeats of unknown function and a consensus PDZ-binding motif that binds to the scaffolding protein INAD (Section 1.05.4.8).

1.05.4.6.2 Channel properties

The properties of the native TRP- and TRPL-dependent currents *in vivo* have been characterized by exploiting null mutants of both genes to isolate the respective currents, providing characteristic biophysical fingerprints (Table 2; Reuss, H. *et al.*, 1997). TRP channels (isolated in *trpl* mutants) are highly selective for Ca^{2+} (P_{Ca}:P_{Na} ~100:1) and have a rather small single-channel conductance (~8 pS) with rapid kinetics (mean open time ~0.5 ms). TRP (but not TRPL) channels are completely blocked by micromolar levels of La^{3+}. TRPL channels, isolated in *trp* mutants are relatively nonselective (P_{Ca}:P_{Na}~4:1) with a conductance of 35 pS and slightly slower channel open times (1–2 ms). The only reported specific blocker is cinnamyl-dihidroxy-cyanocinnamate, with an IC_{50} of 1 μM (Chyb, S. *et al.*, 1999b). An interesting feature of the TRP channel is a pronounced voltage-dependent open channel block by physiological concentrations of Mg^{2+} (IC_{50} ~1 mM). The block is relatively weak around resting potential (−70 mV), but intensifies as the cell depolarizes. This means that the effective single-channel conductance should decrease as the cell depolarizes in response to light, and potentially would seem to be an elegant and economical mechanism for light adaptation (Hardie, R. C. and Mojet, M. H., 1995).

Both TRP and TRPL have also been expressed in heterologous expression systems, indicating that they encode bona fide channels (Vaca, L. *et al.*, 1994; Gillo, B. *et al.*, 1996; Hardie, R. C. *et al.*, 1997; Xu, X. Z. S. *et al.*, 1997). TRPL has been successfully expressed by many groups (Hu, Y. *et al.*, 1994; Harteneck, C. *et al.*, 1995; Gillo, B. *et al.*, 1996; Lan, L. *et al.*, 1996; Hardie, R. C. *et al.*, 1997), and its biophysical properties found to be indistinguishable from those of the native TRPL-dependent current isolated in *trp* mutants (Hardie, R. C. *et al.*, 1997; Chyb, S. *et al.*, 1999b). Together with the complete elimination of the native current by the *trpl* mutation (Niemeyer, B. A. *et al.*, 1996; Reuss, H. *et al.*, 1997), the close functional equivalence of native and heterologously expressed TRPL channels leaves little doubt as to their identification (Hardie, R. C. *et al.*, 1997). Although there is good evidence that TRPL can

Table 2 Biophysical properties of TRP and TRPL channels

A

Permeability ratios	*TRP (in trpl)*	*TRPL (in trp)*	*WT*
P_{Ca}:P_{Cs}	57	4.3	45.1
P_{Mg}:P_{Cs}	15.8	1.4	5.7

B

	γ (pS) (divalent free)	*γ (pS)*	*τ (ms)*	*IC_{50} Mg^{2+} (mM), 0 Ca^{2+}*	*IC_{50} Mg^{2+} (mM), 1.5 Ca^{2+}*	*La^{3+} block (10 μM)*
TRP (in *trpl*)	35	8	2, 0.2	0.28	1.3	Total
TRPL (in *trp*)	70	35	0.4	4	4	None

A: Permeability ratios (P_x:P_{Cs}) derived from bi-ionic reversal potential data. Values expressed with respect to internal Cs^+ (130 mM) and determined in respective mutants, i.e., TRPL channels measured in the *trp* mutant, TRP-dependent channels in *trpl*. Data from Reuss H. *et al.* (1997).

B: Estimates of single-channel characteristics and ion block. Single-channel conductances (γ, pS) derived from noise analysis in both divalent free and physiological Ringer's. Time constant (τ) refer to Lorentzian fits to power spectra. Mg^{2+} block has been determined only in WT (dominated by TRP channels) and *trp* mutant. Data from Hardie R. C. and Minke B. (1994b), Hardie R. C. and Mojet M. H. (1995), Hardie R. C. *et al.* (1997), Reuss H. *et al.* (1997), Raghu P. *et al.* (2000b), and Liu C. H. *et al.* (2007).

associate as a heteromultimer with TRP (Xu, X. Z. S. *et al.*, 1997), it seems questionable whether the *in vivo* light-sensitive TRPL-dependent conductance includes TRP subunits as well. Thus the WT light-sensitive conductance can readily be accounted for by the independent sum of TRP and TRPL, whilst blocking TRP channels with La^{3+} quantitatively mimics the effect of the *trp* mutation leaving TRPL channels indistinguishable from those found in *trp* mutants (Reuss, H. *et al.*, 1997). A third TRP homologue, TRPγ, has also been identified and found to be expressed in the photoreceptors (Xu, X. Z. S. *et al.*, 2000). TRPγ was also reported to form heteromultimers with TRPL (but not TRP) in expression systems and a dominant negative construct suppressed the TRPL-dependent light response *in vivo* suggesting that the native channels might also represent TRPL–TRPγ heteromultimers. However, unlike TRP and TRPL, recent evidence suggests that TRPγ is not particularly eye-enriched (Jors, S. *et al.*, 2006) and until a mutant is generated, its role remains uncertain.

By contrast, it has generally proved very difficult to express TRP, and the few published reports of its biophysical properties in expression studies (Vaca, L. *et al.*, 1994; Gillo, B. *et al.*, 1996; Xu, X. Z. S. *et al.*, 1997) do not closely match the properties of the *in vivo* TRP-dependent current (isolated in *trpl* mutants). This therefore raises the question of whether TRP actually represents a pore-forming channel subunit *in vivo*. This concern has recently been addressed by the identification of a unique aspartate residue (Asp^{621}) within the TRP pore region as the major determinant of Ca^{2+} permeation, most likely forming a ring of four such acidic residues in a tetramer, as in other Ca^{2+}-selective channels. Neutralizing Asp^{621} (to glycine) almost completely eliminated Ca^{2+} permeation *in vivo*, whilst more conservative substitutions resulted in intermediate ionic selectivities (Liu, C. H. *et al.*, 2007). Systematic alteration of pore properties by site-directed mutagenesis of the pore represents the most rigorous demonstration of channel identity, and thus these results conclusively demonstrate that TRP does indeed form a pore-forming subunit of the *Drosophila* light-sensitive channel *in vivo*.

1.05.4.6.3 *trp* and *trpl* phenotypes

Apart from the changes in permeation properties and pharmacology of block, both *trp* and *trpl* mutants have a number of intriguing secondary phenotypes. The original *trp* phenotype is the decay of the response to baseline during maintained illumination, associated with a complete loss of sensitivity that slowly recovers in the dark. After some debate, this now appears to be attributable to the complete loss of PIP_2 due to the failure of Ca^{2+}-dependent inhibition of PLC (see Figure 20 and Section 1.05.6.2). With weaker illumination, or brief flashes, responses in *trp* mutants are superficially similar to WT; however, they have about tenfold reduced sensitivity, their kinetics are slightly slower and fail to accelerate during light adaptation. Indeed, virtually all aspects of light adaptation are lacking, and the loss of response during light adaptation regimes is better described as exhaustion of the excitatory process (Minke, B., 1982). Whilst intracellular recordings originally suggested that quantum bumps were similar in WT and *trp*, the improved resolution of whole-cell recordings clearly showed a reduction in bump amplitude to ~3–4 pA (Niemeyer, B. A. *et al.*, 1996; Henderson, S. R. *et al.*, 2000). Given that the TRPL single-channel current is ~2 pA, this implies that bumps in *trp* usually consist of only one to two channel openings.

By contrast, quantum bumps and macroscopic flash responses in *trpl* mutants are almost indistinguishable from WT, and initially the only phenotypes found in whole-cell recordings of the LIC were changes in ionic selectivity and the complete block of the light response by La^{3+} (Niemeyer, B. A. *et al.*, 1996; Reuss, H. *et al.*, 1997). This suggests that the TRP channels make the dominant contribution to the WT light response, and it has been estimated that ~95% of the DA LIC in flash responses is attributable to TRP (Reuss, H. *et al.*, 1997). However, subsequent studies using prolonged illumination performed under more physiological conditions, using either the ERG or intracellular voltage recordings, revealed further distinct phenotypes. These include a reduced plateau potential, oscillations superimposed on the response and an impaired ability to light adapt to very dim background lights (Leung, H. T. *et al.*, 2000). With the possible exception of the reduced ability to light adapt (see Section 1.05.4.6.4), it remains unclear however, how these phenotypes relate to the known properties of the two channels. Leung H. T. *et al.* (2000) also reported an intriguing genetic interaction between *trpl*, *trp*, and a mutant of the scaffolding protein INAD (Section 1.05.4.8), $InaD^{P215}$, which has a point mutation disrupting its binding to TRP. Specifically, whilst *trpl* and $InaD^{P215}$ mutants have normal or near normal levels of TRP protein, the *trpl*,$InaD^{P215}$ double mutant has greatly reduced (<10%) levels of TRP and an even more profound loss of response, which could not be entirely

accounted for by the loss of protein. This suggests that when TRP is not bound to INAD, it requires TRPL in order to maintain TRP protein levels and to generate significant responses (Leung, H. T. *et al.*, 2000).

1.05.4.6.4 TRPL translocation

Another feature that distinguishes the TRPL from the TRP channel is that the former, like arrestin and G_q, also undergoes a massive light-induced translocation. Translocation of the TRPL protein out of the rhabdomere in response to illumination, and its return in the dark has been shown both by immunocytochemistry and by tracking an enhanced green fluorescent protein (eGFP)-tagged TRPL protein *in vivo* (Bahner, M. *et al.*, 2002; Meyer, N. E. *et al.*, 2006). In the larger fly *Calliphora*, translocation has also been confirmed by quantitative Western blotting of cytosolic and rhabdomeral fractions (Bahner, M. *et al.*, 2002). In *Drosophila*, at least 80% of eGFP-tagged TRPL leaves the rhabdomere during bright illumination with a halftime of 3.25 h, returning rather more quickly in the dark (halftime 1 h). The translocation mechanism appears to require operation of the full transduction cascade, being blocked in *Gαq*, *norpA*, and *trp* mutants, and also by removal of extracellular Ca^{2+}, whilst it is impaired in the *ninaC* and *arr2* mutants (Meyer, N. E. *et al.*, 2006). Importantly, whole-cell recordings confirmed the removal (and return) of functional TRPL channels from the rhabdomeres, assayed by their reversal potential and insensitivity to La^{3+}. One of the physiological consequences of the translocation of TRPL protein out of the rhabdomere following light exposure, namely an impaired inability to adapt to weak background lights, closely mimics one of the *trpl* mutant phenotypes (Section 1.05.4.6.3). A possible explanation for this is that the TRPL channel may be subject to more pronounced Ca^{2+}-dependent inactivation than the TRP channel, and that consequently low levels of Ca^{2+} influx associated with weak background illumination have more effect in inhibiting TRPL channels than TRP channels, and hence this cause less reduction in sensitivity when only TRP is present (Bahner, M. *et al.*, 2002).

1.05.4.7 INAF, a Novel Protein Required for TRP Function

The *inaF* gene encodes a small, highly eye-enriched protein with no homologies to other proteins in the databases and no predicted transmembrane domains. Null *inaF* mutants have substantially reduced (~10% of WT levels) TRP protein levels and a phenotype that resembles that of a *trp* null mutant, whilst TRPL channel function appears intact (Li, C. J. *et al.*, 1999). Interestingly, the residual TRP protein in *inaF* mutants is still localized to the rhabdomeres, yet the phenotype is as severe as in *trp* mutants in which there is no immunodetectable protein. Therefore, although the reduced levels of TRP protein may contribute to the phenotype, Li C. J. *et al.* (1999) suggest that the INAF protein may also have a direct regulatory role in TRP channel function.

1.05.4.8 Scaffolding Protein INAD

Along with translocation, one of the most intriguing recent developments in invertebrate photransduction has been the realization that not only are the molecular elements of the cascade highly compartmentalized within microvilli, but that several key proteins are also organized into a multimolecular signaling complex by a scaffolding protein, INAD (Figure 6). The first mutant allele of *InaD* ($InaD^{P215}$) was isolated by Pak and coworkers, and after it was cloned the gene was found to encode a protein with five so-called PDZ domains (Shieh, B. H. and Niemeyer, B., 1995; Shieh, B. H. and Zhu, M. Y., 1996; Chevesich, J. *et al.*, 1997; Tsunoda, S. *et al.*, 1997). PDZ domains are modules, which anchor a variety of protein targets, typically though not always by a short (three amino acids) C-terminal target sequence (see Figures 6 and 7). The final composition of the complex is still debated, but there is general agreement that a core set of three proteins TRP, PLC, and PKC, are bound to INAD in a stoichiometric (1:1:1:1) manner (Huber, A. *et al.*, 1996a; Tsunoda, S. *et al.*, 1997; Li, H. S. and Montell, C., 2000). Other reported targets include rhodopsin, the second ion channel (TRPL), NINAC (Section 1.05.4.9), which is a class III myosin that has been proposed to link the complex to the actin cytoskeleton, CaM, and the immunophilin FKBP59 (Montell, C., 1999; Goel, M. *et al.*, 2001; Huber, A., 2001). INAD can also form homophilic interactions with itself; together with the likelihood of linkage via TRP, which forms tetrameric channels, this in principle would provide the potential for extended complexes containing multiple channels and PLC molecules (Figure 6).

The precise functional role of the INAD complex (sometimes referred to as signalplex or transducisome) remains uncertain. It has been reasonably speculated

that tethering PLC and the channels together would minimize diffusional delays, thus contributing to the rapid kinetics. It has also been suggested that the INAD complex represents the molecular framework responsible for the quantum bump (Scott, K. and Zuker, C. S., 1998), but definitive evidence for this is lacking. The null $InaD^{1}$ mutant has greatly reduced sensitivity and quantum bumps are much reduced in size (Scott, K. and Zuker, C. S., 1998); however, this could simply reflect reduced levels of microvillar PLC since INAD is also required for targeting PLC to the microvillar membrane (Tsunoda, S. *et al.*, 2001). It is also possible to genetically disrupt specific INAD interactions; for example, the TRP channel's interaction with INAD can be disrupted by mutations either in the TRP-specific PDZ domain on the INAD protein (as in the original $InaD^{P215}$ mutation), or by mutation in the C-terminal PDZ-binding motif of the TRP protein (Li, H. S. and Montell, C., 2000). In either case, there is little, if any, defect in the kinetics or amplification of excitation, although there is a specific deactivation defect (quantum bumps terminate abnormally slowly) in the $InaD^{P215}$ mutant (Shieh, B. H. and Niemeyer, B., 1995; Henderson, S. R. *et al.*, 2000). Most recently, a similar deactivation defect, albeit measured in the ERG, was reported after engineering a point mutation of a key PKC phosphorylation site in the TRP protein, suggesting that the association of TRP with INAD and PKC (also a member of the signalplex) is critical for TRP phosphorylation (Popescu, D. C. *et al.*, 2006) (see also Section 1.05.6.2.2). Whether or not the proximity of PLC and TRP on a molecular scale is also essential for normal excitation, one of the vital roles of INAD is to maintain TRP and PLC and PKC in the microvillus in high concentrations (~100 copies per microvillus) and in stoichiometric relationship. In fact both TRP and INAD are essential for the long-term maintenance of the complexes in the rhabdomeres. Thus, whilst both TRP and INAD are initially correctly targeted to the rhabdomere in the absence of the other, over a period of days, TRP protein disappears from the rhabdomere in *InaD* mutants, whilst INAD protein is similarly destabilized in *trp* mutants (Tsunoda, S. *et al.*, 1997; Li, H. S. and Montell, C., 2000).

1.05.4.9 Myosin Kinase NINAC

The *ninaC* locus encodes two photoreceptor-specific class III myosins characterized by an N-terminus kinase domain followed by a myosin-like domain (Figure 7). A long form (174 kDa) is localized in the rhabdomeres, whilst a short cytosolic variant (132 kDa) is found only in the cell body (Montell, C. and Rubin, G. M., 1988). The rhabdomeric 174-kDa protein may be linked to the F-actin core of the microvillus (Hicks, J. L. *et al.*, 1996). *ninaC* null mutants or mutants lacking the rhabdomeric 174-kDa variant show defects in response termination and light adaptation, including an abnormally large steady-state plateau response (Porter, J. A. *et al.*, 1992; Porter, J. A. and Montell, C., 1993; Hofstee, C. A. *et al.*, 1996; Arnon, A. *et al.*, 1997a), and also undergo light-dependent retinal degeneration (Porter, J. A. *et al.*, 1992). The mechanistic basis for these phenotypes remains uncertain, though the deactivation defect can be attributed, at least in part, to its role as the major CaM-binding protein in the retina (Porter, J. A. *et al.*, 1993) (see Section 1.05.6.2.1). NINAC is also a phosphoprotein and an *in vitro* target for PKC and possibly other kinases. Targeted mutagenesis of two putative phosphorylation sites in NINAC resulted in an unusual ERG phenotype, with slow oscillations in the dark following a bright flash (Li, H. S. *et al.*, 1998). *ninaC* mutants have also been reported to be defective in a putative PKA-mediated modulation of response latency (Chyb, S. *et al.*, 1999a). More recently, *ninaC* mutants have been reported to show defects in the translocation of both arrestin (Lee, S. J. and Montell, C., 2004) (disputed by Satoh, A. K. and Ready, D. F., 2005) and the TRPL channels (Meyer, N. E. *et al.*, 2006), possible indicative of a motor function.

1.05.5 Messengers of Excitation

Genetic and other evidence have clearly established that fly phototransduction involves rhodopsin, G_q protein, and PLC, followed by activation of TRP and TRPL channels; however, the final steps of activation downstream of PLC, and in particular, the messenger of excitation are controversial and have still not been unequivocally resolved.

1.05.5.1 Evidence for Activation by Lipid Messengers

$InsP_3$ is the most familiar product of PIP_2 hydrolysis by PLC, and its major target is the $InsP_3R$ – an intracellular Ca^{2+} release channel found on internal Ca^{2+} stores. Although it was originally widely believed that $InsP_3$-induced Ca^{2+} release from the SMC was an essential step in excitation in

Drosophila, as appears to be the case, for example, in *Limulus* (see Section 1.05.9), most recent evidence suggests it plays no role. Firstly, neither $InsP_3$ nor Ca^{2+} has been found to activate the light-sensitive channels, even when released instantaneously by flash photolysis of caged precursors (Hardie, R. C., 1995; Hardie, R. C. and Raghu, P., 1998). Furthermore, although light induces a massive rise in cytosolic Ca^{2+}, this is almost entirely due to Ca^{2+} influx (see Section 1.05.6.1.1; Peretz, A. *et al.*, 1994; Ranganathan, R. *et al.*, 1994; Hardie, R. C., 1996b). Most importantly, all aspects of phototransduction appear to be completely normal in mutants of the only known $InsP_3R$ gene in *Drosophila* (Acharya, J. K. *et al.*, 1997; Raghu, P. *et al.*, 2000a). Although some pharmacological evidence has implicated the ryanodine receptor (RyR) in phototransduction in *Drosophila* (Arnon, A. *et al.*, 1997b), null mutants of the RyR again failed to shown any discernible phenotype (Sullivan, K. M. C. *et al.*, 2000).

By contrast, genetic evidence, particularly involving mutations of the *rdgA* gene encoding diacylgylcerol kinase (DGK), strongly implicates DAG in the excitatory pathway (Figure 16). The first indication was the finding that both TRP and TRPL channels were constitutively active in the dark in *rdgA* mutants, consistent with activation by build up of DAG by basal PLC activity (Raghu, P. *et al.*, 2000b). Recently, strong evidence for the requisite basal hydrolysis of PIP_2 by PLC has been

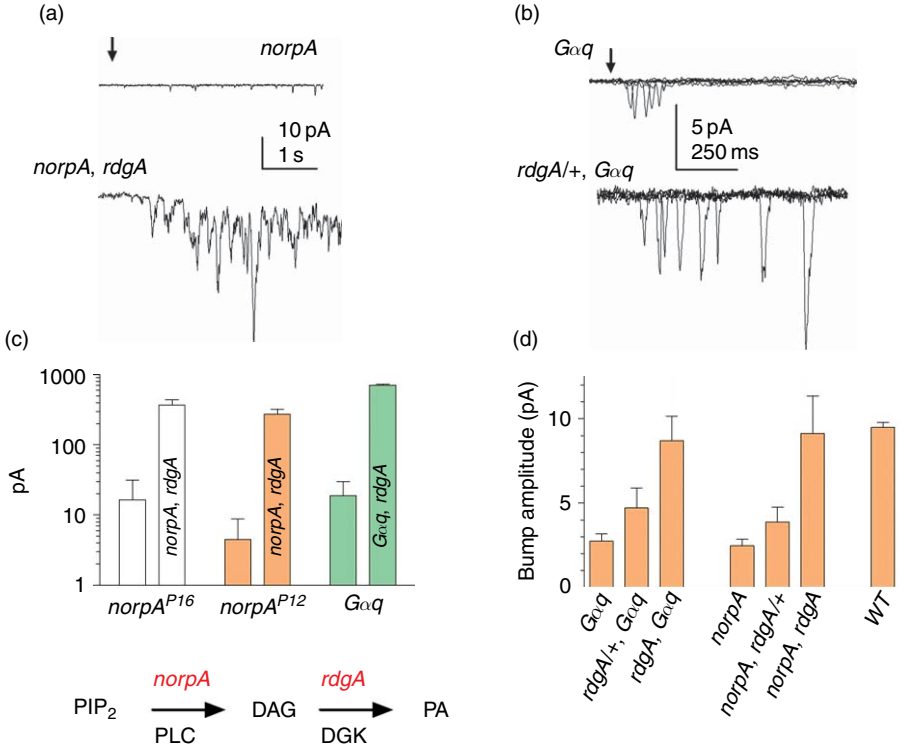

Figure 16 Genetic evidence for excitatory role of DAG. Mutations in DAG kinase (DGK, *rdgA* gene) greatly facilitate responses in PLC and *Gαq* hypomorphs. (a) A bright flash in a severe *norpA* hypomorph (*norpA*^{P12}) elicits no more than a few sporadic 1- to 2-pA bumps; in the double mutant *norpA*^{P12},*rdgA*^{1} the response to the same intensity is enhanced ~100-fold. (b) In a *Gαq* mutant, repeated flashes elicit small ~2-pA quantum bumps (traces superimposed); however, the bump amplitude is greatly increased even in a *rdgA*/+ heterozygote where the DGK levels are reduced by only ~50%. (c) Summary of averaged data (mean ± SEM) for macroscopic response amplitude in two *norpA* alleles (P12 and P16) and also the *Gαq* mutant (left bar, single mutant; right bar, in double mutant combination with *rdgA*) – note the logarithmic scale. (d) Summary of data on quantum bump amplitudes in *Gαq* and *norpA*^{P12}, showing dosage-dependent rescue by the *rdgA* mutation. Below: reference to the roles of PLC and DGK shows how the data can be readily interpreted if it is assumed that DAG is an excitatory messenger. Adapted with permission from Hardie, R. C., Martin, F., Cochrane, G. W., Juusola, M., Georgiev, P., and Raghu, P. 2002. Molecular basis of amplification in *Drosophila* phototransduction. Roles for G protein, phospholipase C, and diacylglycerol kinase. Neuron 36, 689–701.

obtained *in vivo* using the genetically targeted PIP_2 biosensor (Kir2.1 channel) in both WT and *rdgA* mutants (Figure 14 and Section 1.05.4.5.2). A second powerful argument is that DGK mutations massively facilitate the response to light in severe *norpA* or *Gαq* hypomorphs (Figure 16). In such mutants, bump amplitudes are reduced five- to tenfold (Figures 12 and 13) and the macroscopic response to light can be reduced 100- to 1000-fold. However, when combined with the *rdgA* mutation, responses are massively facilitated and quantum bump amplitudes restored to WT levels (Hardie, R. C. *et al.*, 2002). The possibility that pleiotropic effects of the *rdgA* mutation mediate such effects are effectively excluded by finding that even a ~50% knockdown of DGK activity in *rdgA*−/+ heterozygotes (themselves otherwise fully WT in behavior) is sufficient to substantially amplify responses in these PLC and G_q hypomorphic backgrounds (Figure 16, and Hardie, R. C. *et al.*, 2002).

The *Drosophila* TRP channels can also be activated by metabolic inhibition, and activate spontaneously for example in whole-cell recordings made without ATP in the electrode (Hardie, R. C. and Minke, B., 1994b; Agam, K. *et al.*, 2000). Whilst this has been taken as evidence of protein dephosphorylation – possibly of the channels themselves – contributing to their activation (Agam, K. *et al.*, 2000), a recent study found that activation by metabolic inhibition had an absolute requirement for PLC activity, and proposed that the primary mechanism was failure of DGK activity, combined with basal PLC activity, resulting in buildup of DAG (Hardie, R. C. *et al.*, 2004). An apparent additional requirement of Ca^{2+} inferred from the ability of high concentrations of BAPTA to block the spontaneous activation (Agam, K. *et al.*, 2004) may have been due to the suppression of PLC activity by low Ca^{2+} levels, and a previously unrecognized action of BAPTA as an inhibitor of PLC activity (Hardie, R. C., 2005).

Whilst DAG has been strongly implicated by these and other studies, and is now also widely accepted as an activator of several vertebrate TRPC channels (reviewed in: Hardie, R. C., 2003), at least two obstacles remain. Firstly the only data on DGK immunolocalization indicate that it is found predominantly in the SMC and not in the microvilli (Masai, I. *et al.*, 1997). However, the resolution was not sufficient to exclude presence at the base of the microvilli, which would potentially be sufficient to control DAG levels in the microvilli. Secondly, exogenous application of DAG either to photoreceptors or to heterologously expressed TRPL channels has little or no effect (Hardie, R. C., unpublished; Estacion, M. *et al.*, 2001). The only potential agonists yet found to activate the *Drosophila* channels are in fact poly- or monounsaturated fatty acids (PUFAs), such as arachidonic acid or linolenic acid. PUFAs activate TRPL channels in inside-out patches from heterologously expressed channels as well as both TRP and TRPL channels in whole-cell recordings from photoreceptors with an EC_{50} of ~10 μM (Chyb, S. *et al.*, 1999b). More recently, PUFAs, but not DAG have also been shown to activate the only other TRPC family member in *Drosophila*, namely TRPγ (Jors, S. *et al.*, 2006). PUFAs could in principle be released from DAG by DAG lipase or from phospholipids by PLA_2; however, to date there is no evidence for the existence of such enzymes in the transduction cascade in *Drosophila*. Although a mutation in a putative DAG lipase (rolling black out, *rbo*) recently described by Huang F. D. *et al.* (2004) did in fact result in a severe block in phototransduction, details of its phenotype, were not consistent with such a proposed role. Thus, *rbo* mutants were reported to show reduction in light-induced DAG production, interpreted as an apparent inhibition of PLC activity, whilst the mutant flies only stopped responding to light after continuous bright illumination.

One possible resolution to this problem is suggested by quantitative estimates of the rate of PIP_2 hydrolysis in the photoreceptors, again using the Kir2.1 channel as a PIP_2 biosensor. These measurements indicate that a single-photon absorption results in PLC activity at rates sufficient to hydrolyze all the PIP_2 (and probably also the PI and PIP reserve) in a single microvillus within less than 1 s (Figure 14; Hardie, R. C. *et al.*, 2001; 2004). Given that a single microvillus contains several thousand PI, PIP, and PIP_2 molecules, a simple calculation based on the surface area and volume of a microvillus suggests that, locally, DAG concentrations within the microvillus can be expected to reach near millimolar levels. DAG is notoriously insoluble and if the TRP channels respond to DAG levels in this concentration range, it may be experimentally impossible to apply exogenous DAG at such concentrations, whilst the more soluble PUFAs may act as surrogate, nonphysiological agonists on the same channels.

1.05.5.2 PIP_2 Depletion

In addition to mounting evidence for the role of DAG, recent studies have also raised the possibility that PIP_2 reduction may contribute to excitation.

The first indication was the finding that recombinant TRPL channels in inside-out patches, previously activated by application of exogenous PLCβ, could be inhibited by application of PIP_2 (Estacion, M. *et al.*, 2001). However, recordings of light-activated TRPL channel activity, isolated in *trp* mutants, suggest a different picture *in vivo*. In the *trp* mutant prolonged illumination leads to complete loss of PIP_2 in the microvillar membrane, because Ca^{2+} influx via the TRP channels appears to be required for inhibition of PLC activity (see Section 1.05.6.2), but under these conditions the remaining TRPL channels rapidly close and remain profoundly inactivated until PIP_2 is resynthesized (Hardie, R. C. *et al.*, 2001). This collapse of the response is consistent with a role for DAG in excitation, since the substrate for its generation is exhausted, but clearly contrary to what would be expected if PIP_2 depletion directly activated the channels. Interestingly, however, TRP channels behave rather differently. The Ca^{2+} influx required to prevent excessive PIP_2 hydrolysis by PLC can also be blocked by removing extracellular Ca^{2+}: under these conditions flashes of light which deplete a substantial fraction of PIP_2 usually result in a failure of the TRP channels to close after termination of the light flash. A similar failure in response termination can also be observed in mutants of the *rdgB* gene, which encodes an essential component of the PIP_2 recycling pathway (Vihtelic, T. S. *et al.*, 1993; Milligan, S. C. *et al.*, 1997; Hardie, R. C. *et al.*, 2001) (see Section 1.05.7 and Figure 17). Finally, when TRP channels are activated following ATP deprivation they remain active indefinitely, and long after all detectable PIP_2 has disappeared from the microvilli (Gu, Y. *et al.*, 2005). Since large amounts of DAG are also produced under all these conditions, activation cannot necessarily be attributed to PIP_2 depletion alone; however, a hypothesis worth further investigation is that channels may be activated by simultaneous generation of DAG and depletion of PIP_2. For example, the TRP protein (or associated proteins) might incorporate domains capable of binding PIP_2 and DAG (or PUFA); binding to PIP_2 would stabilize the closed state, whilst DAG/PUFA would stabilize the open state.

Further support for the roles of DAG and/or PIP_2 in excitation comes from recent studies of mutants (*laza*) of an eye-enriched phosphatidic acid phosphatase (PAP). More correctly referred to as lipid phosphate phosphohydrolase (LPP), this enzyme catalyzes the reverse reaction from DGK, namely PA to DAG (see Figure 17, Garcia-Murillas, I. *et al.*, 2006; Kwon, Y. and Montell, C., 2006). Analysis of *laza* mutants indicates that LPP acts antagonistically with DGK (*rdgA*) to regulate the levels of DAG and PA. Thus the normally slow response termination in the ERG of a hypomorphic *rdgA* mutant ($rdgA^3$) was accelerated in the $rdgA^3$; *laza* double mutant, but further slowed by overexpression of LPP using a WT *laza* transgene (Garcia-Murillas, I. *et al.*, 2006). Similarly, using an independently generated *laza* mutant, (Kwon, Y. and Montell, C., 2006) found that response amplitudes (measured by ERG) were reduced and response decay times accelerated in *laza* mutants. Similar genetic interactions between *laza* and *rdgA* were also seen in their retinal degeneration phenotypes – in that *laza* mutants suppress, and *laza* overexpression enhances degeneration in *rdgA* (Garcia-Murillas, I. *et al.*, 2006).

On the one hand, these results would appear to support a role for DAG in excitation and degeneration, since *laza* mutations would be expected to decrease DAG levels (at the expense of PA), whilst overexpression of LPP would increase DAG. However, Garcia-Murillas I. *et al.* (2006) also found that PI levels are reduced in *rdgA* mutants, particularly in combination with *laza* overexpression, due, not only to the involvement of PA as substrate for PI recycling (Section 1.05.7), but also because transcript levels of PI synthase, an essential enzyme for PIP_2 recycling were greatly reduced in these mutant backgrounds. Garcia-Murillas I. *et al.* (2006) also noted that whilst PA levels have been shown to be decreased in *rdgA* mutants (a finding which they confirm), DAG levels have been reported to remain unaltered (Inoue, H. *et al.*, 1989), and therefore interpret their results as support for the suggestion that the decrease in PIP_2 may underlie the degeneration, and possibly contribute to the excessive and prolonged activation of TRP channels.

In summary, there is little evidence to support a role for $InsP_3$ in excitation in *Drosophila*, whilst a number of recent studies have suggested that the alternative, membrane-delimited products of PLC activity (i.e., DAG, PUFAs, and PIP_2) are the relevant messengers of excitation. However, this area is still controversial and final resolution of the mechanism of excitation is likely to require, *inter alia*, identification and characterization of lipid-binding sites on the channel molecules, further biochemical analysis of light-induced lipid metabolism, and molecular identification and mutant analysis of any further gene products required for activation.

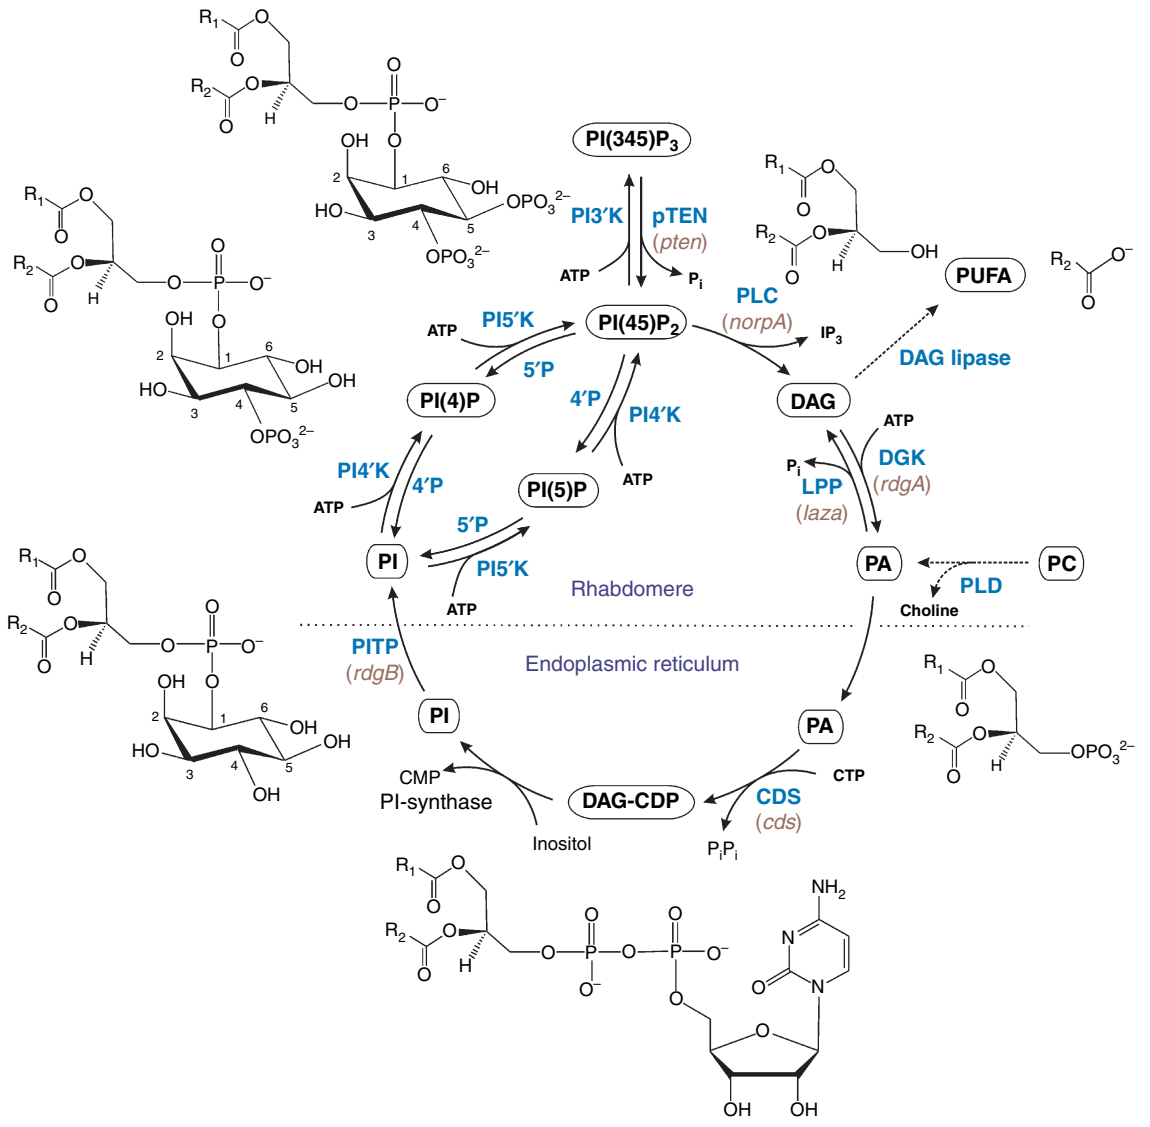

Figure 17 Phosphoinositide cycle. PIP_2 is hydrolyzed by PLC (*norpA* gene), generating diacylgylcerol (DAG) and $InsP_3$. DAG is converted to phosphatidic acid (PA) via DAG kinase (*rdgA*), the reverse reaction (PA to DAG) is catalyzed by LPP (*laza*); DAG may also be converted to PUFAs by a DAG lipase. PA can also be synthesized *de novo* by acylation of glycerophosphate and can be released from phosphatidylcholine (PC) by PLD. PA is combined with CTP to form CDP–DAG via CD synthase (*cds*) in the SMC. This in turn undergoes condensation with inositol to form to phosphatidylinositol (PI) via PI synthase. PI is transported back to the microvillar membrane by a PI transfer protein (*rdgB*). PI is converted to PIP_2 via sequential phosphorylation (PI kinase and PIP kinase) in the microvilli to reconstitute PIP_2. PIP_2 may also be further phosphorylated to PIP_3 via PI3′ kinase and reconverted via a PIP_3-specific lipid phosphatase (pTEN).

1.05.6 Ca^{2+}-Dependent Feedback and Mechanisms of Adaptation

Whilst current evidence argues that the primary agent of excitation is a membrane-delimited lipid messenger, the importance of Ca^{2+} influx via the channels as regulator of phototransduction and mediator of adaptation can hardly be overstated. This was graphically illustrated in some of the first whole-cell recordings from *Drosophila* photoreceptors investigating the effect of removing extracellular Ca^{2+} (Hardie, R. C. 1991b; Ranganathan, R. *et al.*, 1991). Both onset and offset kinetics are greatly slowed, quantum bump amplitudes are reduced about tenfold (Henderson, S. R. *et al.*, 2000), and the peak–plateau transition characteristic of light adaptation is largely abolished (Figure 18).

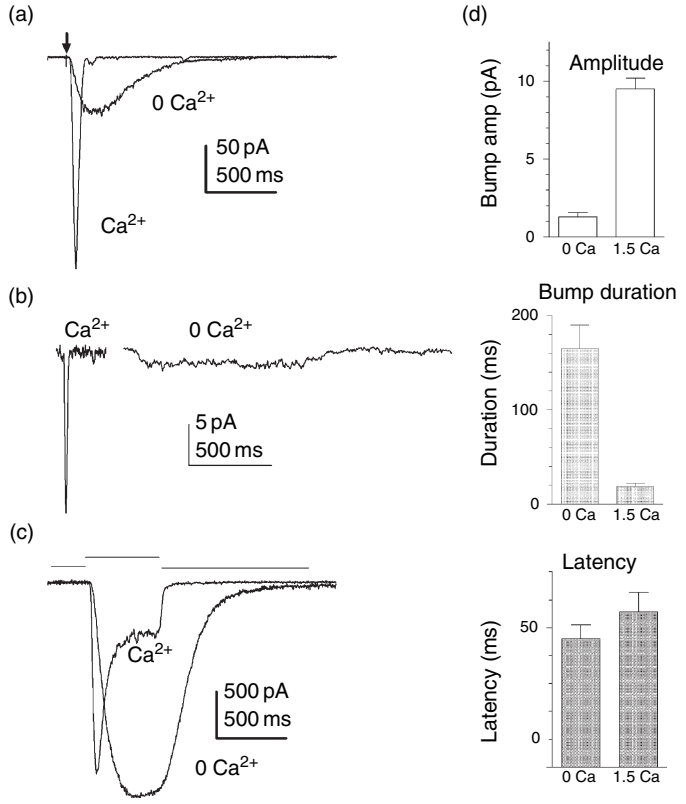

Figure 18 Ca^{2+}-dependent feedback. (a) Responses recorded in normal bath (Ca^{2+}) and after perfusing with EGTA-buffered Ca^{2+}-free Ringer (0 Ca^{2+}) reveal the profound influence of Ca^{2+} influx on the light response. Both rising and falling phases are greatly slowed down suggesting that Ca^{2+} influx mediates both positive and negative feedback. (b) This behavior is also seen at the level of the quantum bumps, which are greatly reduced in amplitude and prolonged in the absence of external Ca^{2+}. (c) Ca^{2+} influx is also essential for light adaptation: the peak-to-plateau transition during a 500 ms stimulus is eliminated in the absence of external Ca^{2+}. (d) Quantum bump parameters; amplitude, duration (half-width), and latency, measured in normal (1.5 mM Ca^{2+}) and Ca^{2+}-free bath. Note that the amplitude is reduced and the duration increased, but the latency is unaltered. For further details, see Henderson S. R. *et al.* (2000).

The mechanisms underlying this Ca^{2+}-dependent regulation are diverse and still not entirely understood, but they include both positive and negative feedback regulation, the latter in particular probably affecting most steps in the transduction cascade. Although Ca^{2+}-dependent positive feedback is arguably the most distinguishing feature of invertebrate phototransduction (in vertebrates, Ca^{2+}-dependent feedback is always operationally negative, see Phototransduction in Rods and Cones), there is little information on the underlying molecular mechanism(s) in *Drosophila*. Electrophysiologically, positive feedback is manifest as a about tenfold increase in the amplitude of the quantum bumps and an even larger increase in the absolute slope of the rising phase of the response. The feedback can be mimicked by cytosolic release of caged Ca^{2+}, which accelerates the light response with a submillisecond latency (Hardie, R. C., 1995). This would suggest that it acts at a very late stage in transduction – either on the channels themselves, and/or PLC which is facilitated by Ca^{2+} in the range from 10 nM to 1 μM (Running Deer, J. L. *et al.*, 1995) (see Sections 1.05.4.5.2 and 1.05.8.2 for further discussion).

1.05.6.1 Ca^{2+} Signals

Crucial to an understanding of Ca^{2+}-dependent feedback is an appreciation of the Ca^{2+} signals actually experienced by the photoreceptors during stimulation.

1.05.6.1.1 Ca^{2+} signals are dominated by Ca^{2+} influx

Ca^{2+} indicator dyes, including fluo-3, Ca orange, or INDO-1, loaded via the patch pipette reveal a massive and rapid light-induced rise in Ca^{2+} (Peretz, A.

et al., 1994; Ranganathan, R. *et al.*, 1994; Hardie, R. C., 1996b). Absolute estimates in *Drosophila*, made using ratiometric dyes indicate that Ca^{2+} concentration is ~160 nM in the dark, and can transiently reach light-induced values of ~50 μM, measured globally throughout the cell (Hardie, R. C., 1996b). The overwhelming majority of this signal derives from Ca^{2+} influx via the light-sensitive channels, since the Ca^{2+} signal is undetectable (Peretz, A. *et al.*, 1994; Ranganathan, R. *et al.*, 1994), or greatly reduced (Hardie, R. C., 1996b) when extracellular Ca^{2+} is removed. However, a small fluorescent signal, in principle representing a rise of ~20 nM free Ca^{2+}, can still be detected with bright illumination under optimal conditions in Ca^{2+}-free solutions (Hardie, R. C., 1996b; Cook, B. and Minke, B., 1999). Whilst this signal is clearly dependent on phototransduction (e.g., it is absent in *norpA* mutants), it was not significantly reduced in $InsP_3R$ mutants (Raghu, P. *et al.*, 2000a), but was eliminated in the absence of external Na^+ (Hardie, R. C., 1996b; Cook, B. and Minke, B., 1999). It therefore can even be questioned whether it represents release from internal stores; alternative possibilities might include release of buffered Ca^{2+} or a dye artefact induced by massive (bio)chemical changes and/or monovalent ion fluxes associated with responses under these conditions.

1.05.6.1.2 Ca^{2+} transients in the rhabdomeres

Notwithstanding the uncertainties concerning the origin and significance of the residual signal detected under Ca^{2+}-free conditions, the Ca^{2+} signal under physiological conditions is clearly predominantly mediated by Ca^{2+} influx via the TRP channels. TRPL channels are also permeable to Ca^{2+} and can sustain a reduced influx signal in *trp* mutants (Peretz, A. *et al.*, 1994; Hardie, R. C. 1996b) until they close following PIP_2 depletion. Both TRP and TRPL channels are localized along the length of the microvilli (Niemeyer, B. A. *et al.*, 1996), and spatial imaging of the Ca^{2+} influx in *Drosophila* also shows influx to be initially localized to the rhabdomeres (Ranganathan, R. *et al.*, 1994). Rather more accurate and informative Ca^{2+} imaging has been made in the larger fly *Calliphora*, using intracellular indicator dye-injection in the intact animal combined with imaging of the rhabdomeres through the fly's own optics (Oberwinkler, J. and Stavenga, D. G., 1998; 2000). By using a range of indicator dyes with different affinities, Ca^{2+} levels in the rhabdomeres were found transiently to reach values well in excess of 200 μM during bright illumination, before rapidly relaxing (within ~100 ms) to steady-state levels of maximally ~10 μM with the brightest illumination. Under light-adapted (LA) conditions, however, because of the reduction in gain associated with adaptation, incremental flashes generate greatly reduced inward currents and the Ca^{2+} transients in the microvilli now reached only ~50–100 μM (Figure 19). Whilst such measurements were made from the whole rhabdomere in *Calliphora*, theoretical considerations suggest that a similar situation should hold in *Drosophila*, and also that similar values are reached at the level of single microvilli in response to single-photon absorptions (Postma, M. *et al.*, 1999). In fact, the Ca^{2+} levels reached in single microvilli are probably even higher, since measurements will inevitably average the responses of both stimulated and unstimulated microvilli. The time course of the microvillar transients is also likely to be faster, as the measured responses will be smeared by the bump latency dispersion. Finally, the Ca^{2+} levels reached in individual microvilli in between photon absorptions in LA cells are likely to be lower than the measured steady-state level, again because this will represent the average of excited and unstimulated microvilli.

1.05.6.1.3 Ca^{2+} buffers and homeostasis

Invertebrate photoreceptors such as *Drosophila* experience more extreme Ca^{2+} levels than almost any other eukaryotic cells. There is relatively little information on how they cope with these levels, which probably reach a steady state of ~10 μM throughout the cell body during maintained illumination. However, appropriate regulation is vital not only for performance, but also because cell death and retinal degeneration rapidly result when levels are either too high or too low (e.g., Sahly, I. *et al.*, 1994; Alloway, P. G. *et al.*, 2000; Kiselev, A. *et al.*, 2000a; Raghu, P. *et al.*, 2000b; Yoon, J. *et al.*, 2000; Wang, T. *et al.*, 2005a; 2005b). By far, the dominant extrusion mechanism is a Na^+/Ca^{2+} exchanger (encoded by the *calx* gene), which is highly expressed in the microvillar membrane, where it can generate electrogenic Na^+/Ca^{2+} currents of at least 100 pA during Ca^{2+} extrusion. *calx* mutants show greatly reduced sensitivity to light, and response inactivation during continued illumination due to the Ca^{2+} overload, as well as severe and rapid light-dependent retinal degeneration due to Ca^{2+} cytotoxicity (Wang, T. *et al.*, 2005b).

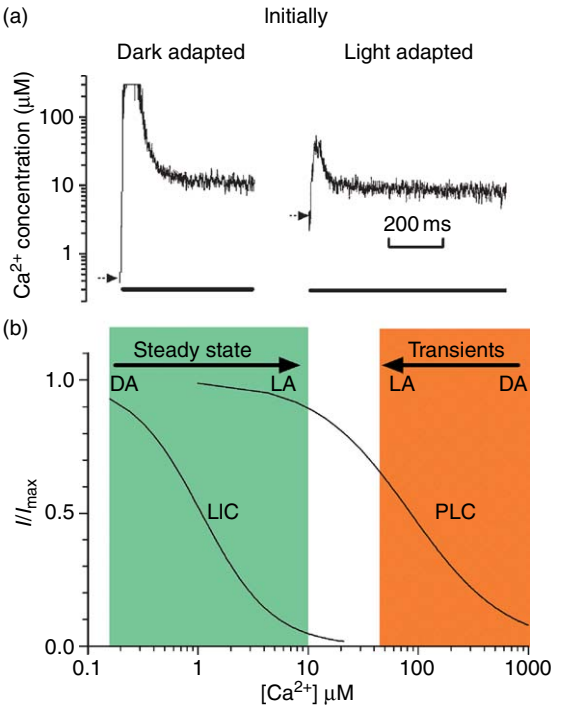

Figure 19 Ca^{2+} signals and adaptation strategy. (a) Ca^{2+} concentration measured in the rhabdomeres of the larger fly *Calliphora* in the intact animal using confocal imaging of the rhabdomeres via the intact optics. Cells were impaled with sharp intracellular microelectrodes containing the dye Oregon Green 5N. Left: In an initially dark adapted cell, Ca^{2+} rises from a submicromolar resting level (arrow) to values in excess of 200 μM (saturation level of the dye), before relaxing to a steady-state level of ~10 μM within ~200 ms. Right: In an initially light adapted cell, Ca^{2+} rises from an initial level of ~3 μM (arrow) to ~50 μM, relaxing now even more rapidly to a new steady state of 10 μM. (b) Based on these findings, as well as on detailed theoretical considerations, the global steady-state Ca^{2+} levels in the microvilli and cell body are believed to vary from ~150 nM in the dark to ~10 μM as background intensity is raised, whilst the transients experienced during incremental flashes (and at the level of microvilli, in response to single photons) vary from ~1 mM in dark adapted cells to ~50 μM in light-adapted cells. The curves show the Ca^{2+} dependence of the inhibition of the light-induced current and channels (LIC) with an IC_{50} of ~1 μM, and of PLC (IC_{50} ~75 μM) determined by manipulation of the Na^+/Ca^{2+} exchanger. This suggests that the gain during steady-state adaptation is primarily determined by the Ca^{2+}-dependent inhibition of TRP channels, whilst the transients experienced during the quantum bumps are sufficient to inhibit PLC, thereby preventing excessive PIP_2 hydrolysis. (a) Adapted with permission from Oberwinkler, J. and Stavenga, D. G. 2000. Calcium transients in the rhabdomeres of dark- and light-adapted fly photoreceptor cells. J. Neurosci. 20, 1701–1709. (b) Adapted with permission from Gu, Y., Oberwinkler, J., Postma, M., and Hardie, R. C. 2005. Mechanisms of light adaptation in *Drosophila* photoreceptors. Curr. Biol. 15, 1228–1234.

The cell body also contains Ca^{2+} stores, which can release enough Ca^{2+} to raise intracellular Ca^{2+} by a few 100 nM when their thapsigargin-sensitive Ca ATPase is inhibited. Although it is debatable whether the stores normally play any direct role in transduction, the Ca^{2+} released following application of thapsigargin or ionomycin is sufficient to facilitate responses to light recorded in Ca^{2+}-free solutions (Hardie, R. C., 1996a). The cell body and microvilli also contain a variety of Ca^{2+}-binding proteins that may function as Ca^{2+} buffers. Firstly, the microvilli have an unusually high level (~0.5 mM) of CaM (Porter, J. A. *et al.*, 1993), which may function as a buffer in addition to other roles described below (Section 1.05.6.2.1). Because of the high surface area-to-volume ratio in the microvillar lumen, low-affinity Ca^{2+} binding to negatively charged phospholipids may also be important. The cell body expresses at least two major Ca^{2+}-binding proteins, calphotin and calnexin. Calphotin is a novel Ca^{2+}-binding protein, which is enriched in the eye and found throughout a large, but distinct central region of the cell body. This region was also found to precipitate Ca oxalate, leading to speculation that it may represent a Ca^{2+}-sequestering sponge (Ballinger, D. G. *et al.*, 1993; Martin, J. H. *et al.*, 1993). Photoreceptors in *calphotin* mutants show severe developmental abnormalities, but calphotin's role as a buffer has not been further investigated (Yang, Y. and Ballinger, D., 1994). Calnexin is a molecular chaperone, and is required, along with the cyclophilin *ninaA* for Rh1 folding and targeting. However, it also appears to play a role as a Ca^{2+} buffer, since Ca^{2+} measurements reveal that abnormally high Ca^{2+} levels are reached during maintained illumination in *calnexin* mutants, whilst the photoreceptors also undergo light-dependent retinal degeneration that cannot be attributed to calnexin's role as a chaperone (Rosenbaum, E. E. *et al.*, 2006).

1.05.6.2 Ca^{2+}-Dependent Negative Feedback

Although a number of Ca^{2+}-dependent feedback targets have been identified in the transduction cascade (Table 3), until recently their respective contribution to light adaptation and response termination was rather poorly defined. A major advance in this respect was made recently by exploring the Ca^{2+} dependence of phototransduction by exploiting the properties of the Na^+/Ca^{2+} exchanger (CalX) to manipulate cytosolic Ca^{2+} in the microvilli (Gu, Y. *et al.*, 2005). The

Table 3 Molecular targets for Ca^{2+}-dependent feedback

Transduction protein	***Biochemical information***	***Function of feedback***
TRP	*In vivo* PKC substrate; contains CaM-binding site (CBS)	Ca^{2+}-dependent facilitation and inhibition
TRPL	*In vitro* PKC substrate; two CBS	Ca^{2+}-dependent inhibition
PLC (*norpA*)	Contains a Ca^{2+}-binding C2 motif. Inhibition is PKC dependent	Ca^{2+}-dependent regulation
INAD	*In vivo* PKC substrate; CBS	Unknown
Arrestin 2	CaMKII substrate	Prevents sequestration with M
Arrestin 1	CaMKII substrate	Unknown
Mediators (Ca^{2+}-dependent enzymes/binding protein)	***Substrates/binding partners***	***Function***
PKC (*inaC*)	TRP, INAD, NINAC	Ca^{2+}- (and DAG)-dependent inactivation
Rh phosphatase (*rdgC*)	CaCaM dependent	Rhodopsin dephosphorylation
CaMKII	Arr2 and Arr1	Pigment cycle
Calmodulin (*cam*)	TRP, TRPL, CaMKII, NINAC, INAD, RDGC	Ca^{2+}-dependent inactivation

Proteins reported to be subject to Ca^{2+}-dependent regulation. Protein targets have been separated into transduction proteins and mediators – i.e., Ca^{2+}-dependent enzymes and binding proteins. See text for further details and reference (Sections 1.05.6 and 1.05.8).

CalX exchanger, which is highly expressed in the microvilli (Wang, T. *et al.*, 2005b), belongs to the NCX family of exchangers, which have a stoichiometry of $3Na^+$:$1Ca^{2+}$, and as such should drive cytosolic Ca^{2+} toward an equilibrium determined by membrane voltage, the transmembrane Na^+ gradient and extracellular Ca^{2+}. By simply varying external Na^+, therefore, it is possible in principle to systematically manipulate cytosolic Ca^{2+} concentration to virtually any desired level. Using this approach it was shown that the LIC was sensitively inhibited by Ca^{2+} in the range 0.1–10 μM with an IC_{50} of ~1 μM Ca^{2+} (Gu, Y. *et al.*, 2005). Raising Ca^{2+} in this range in the dark also quantitatively mimicked the major features of light adaptation (gain reduction, parallel shift of V/log I curves and response acceleration). In marked contrast, PLC activity, monitored using the PIP_2 biosensor channels (Kir2.1), was completely unaffected over this range and was only inhibited by much higher Ca^{2+} levels (IC_{50} ~ 75 μM) indicating that the major features of light adaptation are mediated downstream of PLC (Figure 19, Gu, Y. *et al.*, 2005). An obvious target is the TRP channel that was also found to be inhibited by Ca^{2+} with an IC_{50} of ~1 μM. The very rapid time constant (1–2 ms) of Ca^{2+}-dependent inactivation of TRP, previously determined by applying hyperpolarizing voltage steps or by release of caged Ca^{2+}, suggests a direct mechanism, possibly with the involvement of CaM (Hardie, R. C. and Minke, B., 1994a; Hardie, R. C., 1995). These results thus suggested that the major features of light adaptation appear to be accounted for by Ca^{2+}-dependent inhibition of the light-sensitive channels, the final output stage of the transduction cascade.

Whilst apparently not directly contributing to light adaptation, the inhibition of PLC activity by higher levels of Ca^{2+}, which probably occur only during the Ca^{2+} transients, appears to be an essential mechanism to prevent depletion of PIP_2 during illumination. This inhibition fails not only in the absence of external Ca^{2+}, but also in *trp* mutants, apparently because the reduced Ca^{2+} influx through the less abundant, and less Ca^{2+}-permeable TRP channels is insufficient to generate the high Ca^{2+} levels required to inhibit PLC activity. The evidence for this again came from experiments using Kir2.1 biosensor channels to monitor PIP_2 hydrolysis (Figure 20): under normal conditions, illumination equivalent to bright daylight results in only very modest reductions of PIP_2 levels in the rhabdomere; however, in *trp* mutants even much weaker illumination results in hydrolysis of virtually all detectable PIP_2 (Hardie, R. C. *et al.*, 2001), with an intensity dependence similar to that of the *trp* decay phenotype (Hardie, R. C. *et al.*, 2004). The exhaustion of PLC substrate (PIP_2) due to failure of Ca^{2+}-dependent

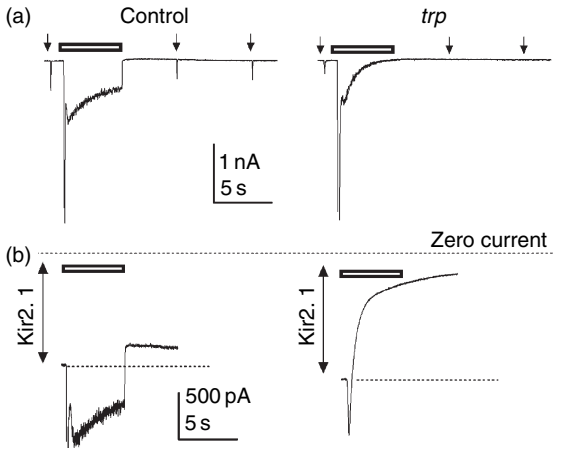

Figure 20 The *trp* decay phenotype is associated with depletion of PIP_2. (a) Whole-cell recordings of response in wild type (WT) (control) and *trp* mutant to a 5 s light stimulus (~30 000 photons per second). Whilst the WT response shows the typical peak–plateau transition due to light adaptation, the response in *trp* decays to baseline. Furthermore, responses to brief test flashes are completely eliminated following the decay in *trp*. (b) The same stimulus, now applied to WT and *trp* mutants expressing the PIP_2-sensitive Kir2.1 channel (see Figure 14). In both cases, the constitutive current of 1–2 nA (double arrows) indicates the response of Kir2.1 to prevailing dark levels of PIP_2. In the WT fly, following illumination there is only a minor reduction in the Kir2.1 current; however, in *trp* the Kir2.1 current is almost entirely suppressed, indicating hydrolysis of the majority of PIP_2. This suggests that Ca^{2+} influx via the TRP channel is required to inhibit PLC activity, and that failure of this inhibition leads to a catastrophic loss of PIP_2, accounting for the *trp* phenotype (Hardie, R. C. *et al.*, 2001).

inhibition of PLC activity thus provides a satisfying explanation for the long debated transient receptor potential *trp* phenotype, which had previously been attributed to depletion of intracellular Ca^{2+} stores (Cook, B. and Minke, B., 1999) or Ca^{2+}-/CaM-dependent inactivation of the TRPL channel (Scott, K. *et al.*, 1997).

The mechanism by which such high levels of Ca^{2+} inhibit PLC activity remains unsolved. Gu Y. *et al.* (2005) also found that PIP_2 levels were depleted by illumination in the PKC mutant *inaC* even more sensitively than is the case in the *trp* mutant, suggesting that the inhibition of PLC is PKC dependent (see Section 1.05.6.2.2).

1.05.6.2.1 Calmodulin

Effects of Ca^{2+} are often mediated by small Ca^{2+}-binding proteins (EF hand proteins), several of which have been implicated in feedback control in vertebrate rods and cones (see Phototransduction in Rods and Cones). In *Drosophila*, however, only one, the ubiquitously expressed CaM, has been implicated in phototransduction, where it acts on several target proteins (Table 3). CaM is highly localized in the microvilli, where it is expressed at unusually high levels (~0.5 mM), potentially enough to function as a Ca^{2+} buffer in addition to more direct roles (Porter, J. A. *et al.*, 1993). The major CaM-binding protein in the eye is the NINAC class III myosin (Section 1.05.4.9) (Porter, J. A. *et al.*, 1992), and the concentration of CaM in the microvilli is greatly reduced in *ninaC* mutants lacking the microvillar 174-kDa splice variant (Porter, J. A. *et al.*, 1993). These $ninaC^{\Delta 174}$ mutants also have a response deactivation defect and an abnormally large plateau response, which appears to be largely attributable to the reduced CaM level, since it can be mimicked in a mutant in which the CaM-binding site (CBS) alone has been deleted from the NINAC protein (Arnon, A. *et al.*, 1997a).

Further insight into CaM function has come from analysis of CaM hypomorphic mutants (*cam*) expressing less than 10% of the normal protein levels. *cam* mutants have even more pronounced defects in response termination than *ninaC*, and the kinetics of response termination no longer show an obvious dependence on external Ca^{2+} concentration (Scott, K. *et al.*, 1997). Closer examination revealed that the slow responses are predominantly a consequence of multiple bump trains in response to single-photon absorptions. Since these are similar to responses in *arr2* mutants (Figure 10), and are more or less abolished on a $G\alpha q$ mutant background, Scott K. *et al.* (1997) concluded that the defect was upstream of G protein and represented a defect in rhodopsin inactivation. They also found that the CaMKII phosphorylation of Arr2 was largely abolished in these flies. As discussed above (Arrestin Phosphorylation) however, Arr2 phosphorylation *per se* is not required for M inactivation by Arr2, so this result implies either an alternative role of CaM in M inactivation, or, as appears to be the case in the $Arr2^{S366A}$ mutant (which lacks the CaMKII phosphorylation site), that Arr2 in these flies becomes unavailable due to permanent sequestration in M–Arr2 complexes. As discussed in Rhodopsin Kinase and Phosphatase, another CaM target is rhodopsin phosphatase (encoded by *rdgC*), which is a Ca–CaM-dependent enzyme, though again the dephosphorylation of rhodopsin is not believed to impact directly upon the light response.

Both TRP and TRPL proteins also have one or more CBSs (Warr, C. G. and Kelly, L. E., 1996; Chevesich, J. *et al.*, 1997) and both channels are subject to Ca^{2+}-dependent inactivation (Hardie, R. C. and Minke, B., 1994a; Reuss, H. *et al.*, 1997; Scott, K. *et al.*, 1997). The TRP protein has one consensus CBS in the C-terminal; peptide fragments containing this region bind CaM in a Ca^{2+}-dependent manner *in vitro* (Chevesich, J. *et al.*, 1997), but the role of the TRP CBS has not been analyzed *in vivo*. *In vitro* studies indicate that one of the two CBS's in TRPL is conventional, binding CaM in a Ca^{2+}-dependent fashion, whilst the other (CBS2) binds the Ca^{2+}-free form of CaM, with dissociation occurring at high Ca^{2+} concentrations (>10 μM) (Warr, C. G. and Kelly, L. E., 1996). Warr C. G. and Kelly L. E. (1996) also found that CaM binding to the conventional CBS1 was modulated by both PKA and PKC phosphorylation *in vitro*. Scott K. *et al.* (1997) reported that transgenic flies expressing TRPL protein in which CBS1 had been deleted had abnormally long light responses with reduced Ca^{2+}-dependent inactivation.

1.05.6.2.2 Protein kinase C INAC

An eye-enriched PKC is a core member of the INAD signaling complex (Figure 6, Section 1.05.4.8), and is encoded by the *inaC* gene (Smith, D. P. *et al.*, 1991). The *inaC* PKC is a classical PKC with >50% identity to vertebrate PKC*β*s and PKC*α*s. Like them, it is presumed to be activated by a combination of DAG and Ca^{2+} via its two putative C1 domains (DAG binding) and one Ca^{2+}-binding C2 domain (reviewed in Shieh, B. H. *et al.*, 2002). INAC has at least two known *in vivo* substrates in the eye, namely the TRP channel and the INAD scaffolding protein (Huber, A. *et al.*, 1996b; 1998; Liu, M. *et al.*, 2000). The TRPL protein and the class III myosin NINAC have also been reported as *in vitro* targets for PKC phosphorylation (Warr, C. G. and Kelly, L. E., 1996; Li, H. S. *et al.*, 1998).

The *inaC* mutant has a specific deactivation defect, with flash responses showing a residual tail that decays slowly over 1–2 s (Figure 10) (Smith, D. P. *et al.*, 1991; Hardie, R. C. *et al.*, 1993). The deactivation phenotype is masked in recordings made in Ca^{2+}-free solutions (i.e., WT and *inaC* mutant responses are now similar), consistent with a defect in Ca^{2+}-dependent inactivation (Ranganathan, R. *et al.*, 1991). Although the deactivation defect in macroscopic responses resembles that in the *arr2* mutant, in *arr2* this results from each photon giving rise to a train of apparently normal bumps (Scott, K. *et al.*, 1997), whilst in *inaC* the defect occurs at the level of individual quantum bumps, which also show a similar waveform (Figure 10, Hardie, R. C. *et al.*, 1993). During sustained bright illumination, the response in *inaC* eventually decays to baseline, reminiscent of the *trp* phenotype (Hardie, R. C. *et al.*, 1993). Experiments using the Kir2.1 PIP_2 biosensor indicated that such responses are associated with a complete loss of PIP_2. This was interpreted as a requirement for PKC for the Ca^{2+}-dependent inhibition of PLC (Gu, Y. *et al.*, 2005). Failure to terminate PLC activity may thus explain the major features of the *inaC* phenotype:

1. the prolonged response, which could be interpreted as prolonged production of excitatory messenger (DAG and/or PIP2 reduction), and
2. the response decay with prolonged illumination due to PIP_2 depletion.

The mechanism by which PKC might inactivate PLC remains unclear, since PLC is not believed to be a direct substrate of PKC. However, since PLC is coupled to INAD in the signalplex, one possibility is that PLC activity could be modulated indirectly by the phosphorylation of INAD.

Recently, PKC was also shown to have an additional, and separable effect on the TRP channel. Popescu D. C. *et al.* (2006) identified a PKC phosphorylation site (Ser^{982}) on the TRP protein, and found that flies expressing TRP channels in which the site was mutated to alanine (TRP^{S982A}) showed a deactivation defect. This deactivation phenotype was less pronounced than that in an *inaC* null mutant, but was very similar to that observed in the $InaD^{P215}$ mutant, which has a point mutation in the PDZ domain responsible for binding TRP (Shieh, B. H. and Zhu, M. Y., 1996). This suggests that the association of TRP with INAD is required for its efficient phosphorylation by PKC. Despite this demonstration of PKC's role in TRP channel termination, it is important to note that the Ca^{2+}-dependent inhibition of the TRP channel is still essentially unaltered in *inaC* mutants (Gu, Y. *et al.*, 2005).

1.05.7 Phosphoinositide Metabolism

Maintenance of the substrate for PLC, PIP_2 is crucial to the functioning of the transduction cascade, as witnessed by the loss of all response when PIP_2 levels collapse, after failure of the Ca^{2+}-dependent inhibition of PLC in the *trp* mutant. PIP_2 recycling involves

a number of steps, summarized in Figure 17, which are believed to take place partly in the microvillar membrane and partly in the ER (i.e., the underlying SMC). Following complete depletion of PIP_2 in the rhabdomere by illumination in the *trp* or *trpl;trp* mutant, PIP_2 levels are restored with a halftime of ~60 s, as monitored either by Kir2.1 channels (see Figure 14), or by the time course for the recovery of the light response in the *trp* mutant (Hardie, R. C. *et al.*, 2001; Hardie, R. C. *et al.*, 2004). Indirect arguments suggest that the final steps in the microvilli (sequential phosphorylation of PI by PI and PIP kinases) are likely to be fast (seconds or subsecond), supplying PIP_2 essentially on demand (Hardie, R. C. *et al.*, 2001). This suggests that the rate-limiting step in recycling is likely to reside in a different part of the cycle, possibly slow transfer of lipids (e.g., PI) between the microvillar membrane and the ER, which form separate membrane containing compartments.

1.05.7.1 rdgA, Cytidine-5′-Diphosphate – Diacylglcerol Synthase, and Phosphatidylinositol Synthase

The first step in PI recycling after PIP_2 hydrolysis is the phosphorylation of DAG by DGK (encoded by *rdgA*) to form phosphatidic acid (PA), which also appears to be a key event in the termination of the light response (Section 1.05.5.1). As discussed in Section 1.05.5.2, the reverse reaction (dephosphorylation of PA to DAG) is catalyzed by LPP. The balance of activity between DGK and LPP appears to be crucial in determining the amount of PA available for PI recycling, and accordingly, *rdgA* mutants have significantly reduced PI and PIP_2 levels (Hardie, R. C. *et al.*, 2004; Garcia-Murillas, I. *et al.*, 2006). Recent evidence, suggests that PA derived from DAG is the major source of PA for PI recycling in the photoreceptors (Garcia-Murillas, I. *et al.*, 2006), but it may not be the only source. PA can be synthesized *de novo* (by acylation of glycerophosphate) and can also be generated by hydrolysis of phosphatidylcholine (PC) by the action of phospholipase D (PLD). Two recent studies of a *Drosophila* PLD mutant have suggested that PA derived from PC may also play a role in phototransduction and/or PI recycling (Lalonde, M. M. *et al.*, 2005; Kwon, Y. and Montell, C., 2006). However, an earlier biochemical study failed to find any evidence for involvement of PLD in PA synthesis in the *Drosophila* eye (Inoue, H. *et al.*, 1989).

PA is combined with CTP to form CDP–DAG by CDP–DAG synthase. A mutant in an eye-enriched isoform of this enzyme (*cds*) has a rather similar phenotype to *trp*, showing a loss of response after repeated stimulation, which could be restored by providing PIP_2 to the cell via the patch pipette (Wu, L. *et al.*, 1995). Strong evidence for essentially irreversible depletion of PIP_2 during continuous illumination was also provided by expressing the PIP_2 Kir2.1 biosensor channels in *cds* mutants (Hardie, R. C. *et al.*, 2002). In common with other mutants in the PI recycling pathway, *cds* mutants also undergo a light-dependent degeneration, which is rescued by the *norpA* (PLC) mutation PLC (Wu, L. *et al.*, 1995).

The next step in the PI cycle is the condensation of inositol and CDP–DAG to form phosphatidylinositol (PI) via the enzyme PI synthase. *Drosophila* contains only one PI synthase gene, and interestingly, its transcript levels are significantly reduced in the *rdgA* mutant and almost eliminated when LPP (*laza*) is overexpressed on the *rdgA* background (Garcia-Murillas, I. *et al.*, 2006). This suggests that PA, which is also severely reduced in these genetic backgrounds, may be a transcriptional regulator of this gene.

1.05.7.2 rdgB and Phosphatidylinositol Kinases

The reactions catalyzed by CDP–DAG synthase and PI synthase are presumed to take place in an ER compartment, probably the SMC. PI is then believed to be returned to the microvillar membrane by a PI transfer protein (PITP) encoded by the *rdgB* gene (Vihtelic, T. S. *et al.*, 1991; 1993), originally isolated as another light-dependent retinal degeneration mutant. Unlike previously characterized PITPs, which are soluble ~35 kDa proteins, RDGB protein is a 161kDa integral membrane protein. However its N-terminal has ~40% identity with the soluble PITP proteins, and in the meantime, mammalian homologues of *Drosophila rdgB* have been discovered, defining a new class (class II) of mammalian PITP proteins with similar topology (reviewed in Cockcroft, S., 2001).

Experiments with PIP_2 biosensors confirmed that PIP_2 recycling is effectively blocked in *rdgB* mutants (Hardie, R. C. *et al.*, 2001); however, there are indications that RDGB may have additional roles in the photoreceptors. For example, a point mutation in the PI transfer domain (T59E) restored PI transfer capability in an in *vitro* assay, but still resulted in a

dominant retinal degeneration phenotype, and in reduced levels of rhodopsin (Milligan, S. C. *et al.*, 1997). More generally, there is considerable evidence that mammalian *rdgB* homologues play multiple roles in membrane trafficking, including vesicle biogenesis and regulated exocytosis (Cockcroft, S., 2001; Allen-Baume, V. *et al.*, 2002).

Finally, PI must be sequentially phosphorylated by PI kinase and PIP kinase. There are several such kinases in the *Drosophila* genome, but which of them are involved in photoreceptors has yet to be unequivocally determined. The conventional route for PIP_2 synthesis would include phosphorylation of PI to PI(4)P by PI-4 kinase, followed by phosphorylation by a type I PIP kinase to PI(4,5) P_2. There are two type I PIP kinases in *Drosophila*, and one of these (*skittles*) has recently been implicated in the photoreceptors since *skittles* mutations were reported to enhance degeneration in *rdgA* (Garcia-Murillas, I. *et al.*, 2006).

1.05.8 Molecular Strategies of Quantum Bump Generation and Adaptation

As emphasized in the introduction, not only can *Drosophila* and other arthropod photoreceptors reliably detect single quanta of light with extremely fast response kinetics, but also they are able to light adapt over the full range of daylight light intensities. Although we do not yet fully understand the mechanism of channel activation and the precise mechanisms of Ca^{2+}-dependent regulation, our current knowledge of the transduction cascade allows us to draw some general conclusions about the strategies involved in achieving in this performance. At any one adaptational state the voltage-clamped macroscopic flash response is remarkably linear, simply representing the summation of the underlying quantum bumps (Figure 2, Henderson, S. R. *et al.*, 2000). The bumps themselves, however, are extremely nonlinear events with many of the characteristics of an action potential, including a threshold, positive and negative feedback and a refractory period. A key to understanding how these bumps are generated, and continue to be generated during light adaptation, is the extreme compartmentalization provided by the microvilli and possibly the ultrastructural organization of the INAD complex.

1.05.8.1 Compartmentalization and Local Signaling

The suggestion, that the signal transduction machinery driving single-photon responses is largely restricted to a single microvillus, dates back to observations that response saturation occurs at light levels equivalent to each microvillus absorbing just a single photon (Howard, J. *et al.*, 1987; Hochstrate, P. and Hamdorf, K., 1990). This is supported by the close congruence of the number of channels activated during a bump (~15) with biochemical estimates of the number (25) of TRP tetramers in a microvillus (Huber, A. *et al.*, 1996a). The restriction of activation to a single microvillus is also consistent with the relatively slow lateral diffusion expected in a membrane-delimited cascade, which is likely to prevent significant diffusion beyond the boundary of one microvillus during the relatively short latent period of the bump (Figure 21).

Each of the ~30–50 000 microvilli represents a tiny volume, ~1–2 μM in length and about 60 nm in diameter. The lumen of the microvillus is connected to the massive cell body via a narrow neck (Figure 1) allowing diffusional exchange of Ca^{2+}. The membrane of a single microvillus is densely packed with about 1000 rhodopsins, and contains only a limited number of the signal transduction components: estimated at about 50 G proteins, ~100 PLCs, ~25 TRP, and ~2 TRPL channels (Figure 21, Huber, A. *et al.*, 1996a). In *Drosophila* it is likely that only the G proteins and lipids are freely diffusible. In contrast, PLC and TRP channels are part of the INAD signaling complex (Figure 6, Section 1.05.4.8), which itself may be tethered to the cytoskeleton rendering it effectively immobile. Furthermore, by analogy to other arthropods (Goldsmith, T. H. and Wehner, R., 1977), it seems likely that rhodopsin itself is immobile on the timescale of transduction. Therefore G proteins are likely to act as diffusible shuttles that transduce the signal from the active M to the PLCs (Bahner, M. *et al.*, 2000). Importantly, a single rhodopsin can sequentially activate several G proteins, thereby amplifying the signal. The approximately fivefold reduction in bump amplitude in hypomorphic $G\alpha q$ mutants (Figure 12), where there is on average less than one G protein per microvillus, suggests that there may be five or so G proteins activated per rhodopsin, with an estimated minimal activation rate of 100–200 G proteins per second. After some delay, and at some distance from the activated rhodopsin, PLC molecules will be activated

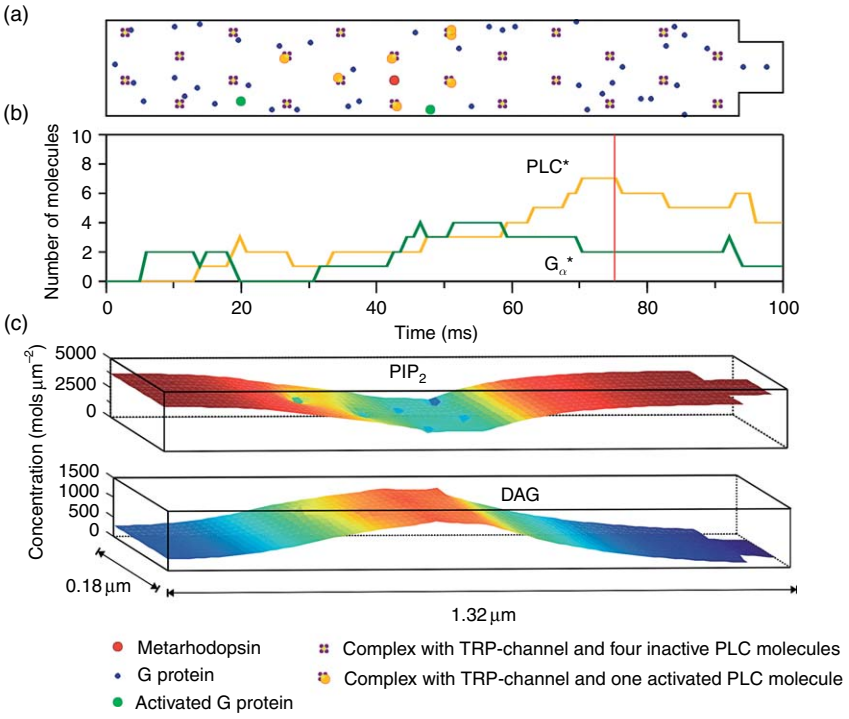

Figure 21 Stochastic modeling of the cascade. (a) Stochastic simulation (random walk encounter) of the membrane surface of a single microvillus, 75 ms after the absorption of a single photon. In the 75 ms since absorption of a single photon, the active metarhodopsin (red) has activated 10 G proteins, eight of which have encountered and activated a PLC (yellow), and two of which (green) are still freely diffusing in the membrane. Two PLCs have also already deactivated due to the PLC-activated GTPase activity of $G_q\alpha$. (b) Time course of the numbers of activated G proteins and PLC as a function of time after photon absorption. (c) Estimated levels of PIP_2 and DAG over the surface of the microvillus generated after 75 ms by the activated PLC molecules. The simulation has used best estimates of the numbers of G proteins (50) and PLC (100) in the microvillus and typical values for diffusion coefficients of G proteins and membrane lipids from the literature. Note that, whilst finite levels of DAG have already reached ~70% of the surface area of the microvillus, no significant diffusion beyond the microvillar boundaries has occurred by this time (Postma, M. and Hardie, R. C., unpublished). According to the model of positive feedback suggested in Section 1.05.8, once the first TRP channel opens (with relatively high DAG threshold), Ca^{2+} influx floods the microvillus within ~5 ms and facilitates activation of the remaining TRP channels to what were previously subthreshold levels of DAG (or derivative).

by $G_q\alpha$ subunits, and will start producing DAG, amplifying the signal further. DAG (or its derivative) will spread along the length of the microvillus and ultimately activate ~15 TRP channels (Figure 21).

1.05.8.2 Fast Nonlinear Response Kinetics

The high Ca^{2+} permeability of the TRP channels and the restricted luminal volume of the microvillus results in Ca^{2+} rising as high as 1 mM throughout the microvillus during a single-photon response (see Section 1.05.6.1.2, Figure 19, Postma, M. *et al.*, 1999; Oberwinkler, J. and Stavenga, D. G., 2000). This overwhelming Ca^{2+} rise is accompanied first by rapid facilitation, closely followed by complete inactivation of the current. Both the positive and negative feedback dominantly shape the waveform of the quantum bump (Figure 18).

The mechanism of facilitation is not known, but it is lacking in the *trp* mutant and therefore only appears to affect TRP channels. A plausible speculation is that it represents a Ca^{2+}-dependent shift in the affinity of the TRP channel for the active ligand, dramatically increasing its sensitivity, analogous perhaps to the shift in affinity to cGMP of the vertebrate CNG channels (Hsu, Y. T. and Molday, R. S., 1993). On this model, once the first channel opens, Ca^{2+} will flood the microvillus, thus further activating the TRP channels, which had been exposed to what were previously only subthreshold concentrations of the

excitatory lipid messenger (e.g., DAG). Another possibility is the facilitation of PLC by Ca^{2+} (Running Deer, J. L. *et al.*, 1995; Hardie, R. C., 2005).

Most of the components of the phototransduction cascade appear to be subject to Ca^{2+}-dependent inactivation (Section 1.05.6.2, Table 3). Firstly, Ca^{2+}-dependent inactivation of the light-sensitive channels TRP and TRPL, either directly, or via CaM (Section 1.05.6), terminates the LIC (Hardie, R. C. and Minke, B., 1994a; Gu, Y. *et al.*, 2005). Secondly, the Ca^{2+}- and PKC-dependent inhibition of PLC is crucial to prevent further production of DAG and depletion of PIP_2 (Hardie, R. C. *et al.*, 2001; Gu, Y. *et al.*, 2005). Finally, recent studies strongly suggest that inactivation of *Drosophila* metarhodopsin by Arr2 is also dependent on Ca^{2+} influx (Liu, C. H. *et al.*, in preparation). The requirement of Ca^{2+} influx for PLC and metarhodopsin inactivation has an elegant logic in that the upstream signals will only be terminated after the channels have been activated.

In summary, the key to fast response kinetics is a combination of the autocatalytic positive feedback loop caused by TRP channels leading to a massive Ca^{2+} influx in the restricted luminal volume of the microvillus, which then rapidly inactivates the cascade. Within 10–20 ms of the first channel opening, the single-photon response peaks and is then terminated with a time constant of about 8 ms. This contrasts with responses measured without Ca^{2+} influx, which peak at about 200 ms and have a decay time constant of about 200 ms with a about tenfold reduction in quantum bump amplitude (Figure 18, Henderson, S. R. *et al.*, 2000). In addition, two further important concepts need to be considered, namely quantum bump latency and the refractory period.

1.05.8.3 Quantum Bump Latency

After successful photon absorption, there is a finite delay before the response becomes apparent (e.g., Figure 2). This bump latency, with an average of ~45 ms, represents the time needed to open the first channel after photon absorption. Unlike vertebrate rods, which have rather invariant latencies, the bump latency in *Drosophila* is highly variable (20–100 ms), signifying on the one hand the stochastic nature of the phototransduction cascade, and on the other an effective threshold (and/or high cooperativity) for channel activation.

The stochastic variability in latency presumably originates from the low number of G proteins and PLC molecules activated during the latent period of the quantum bump. Indeed, stochastic modeling of the cascade, based on realistic diffusion coefficients for G protein and lipids can accurately model the latency and its variability (Postma, M. and Hardie, R. C. unpublished, Figure 21). Modeling also indicates that the latency should allow sufficient time for finite quantities of a putative lipid messenger of excitation to spread by lateral diffusion throughout most of the microvillus. This may help to ensure that the majority of the TRP channels in the microvillus are activated by the Ca^{2+}-dependent positive feedback once the first channel has opened.

As well as contributing to a large gain, such a locally saturated all-or-none response could also provide an excellent mechanism for ensuring reproducibility of the single-photon response, which over the cell has a coefficient of variance of ~0.4 (Henderson, S. R. *et al.*, 2000). The variability in even this relatively tight distribution may result from variability between microvilli, because single bumps repeatedly activated in the same microvillus are even more reproducible in amplitude (Scott, K. and Zuker, C. S., 1998). This performance may be achieved however, as a trade-off against the speed of the response, since the latency distribution is somewhat slower and broader than the quantum bump waveform, and hence represents a major constraint on the macroscopic response kinetics (Figure 2).

1.05.8.4 Refractory Period

Another potentially important consequence of the microvillar design is that the massive Ca^{2+} influx renders the microvillus inactive for a refractory period of about 100 ms. Only when the Ca^{2+} is cleared from the microvillus and the inactivation is removed will it be responsive again. Clearance of Ca^{2+} is predicted to occur very quickly (<100 ms) by a combination of diffusion into the cell body and the Na^+/Ca^{2+} exchanger, which acts very powerfully on the microvillus because of the high surface area-to-volume ratio.

An indication of this refractory period is provided by at least two lines of evidence. Firstly, when a carefully calibrated flash is delivered, just sufficient to activate every microvillus, then a second flash delivered immediately afterward is completely ineffective. However, when delivered after ~80 ms it can generate an additional response (Hochstrate, P. and Hamdorf, K., 1990). Secondly, in certain mutants (e.g., *arr2* and *cam*), activated metarhodopsin fails to

inactivate. In vertebrates, such mutants generate long-lasting quantum bumps that fail to terminate normally (Chen, J. *et al.*, 1995). However, in *Drosophila arr2* or *cam* mutants, single photons elicit a train of quantum bumps separated by an interbump interval of ~100 ms (e.g., Figure 10), but each quantum bump in the train terminates normally and is essentially indistinguishable from a WT bump (Scott, K. *et al.*, 1997). The interbump interval in such trains can thus be thought of as representing the refractory period during which activated rhodopsin can generate no response, but once this is over a second quantum bump can be generated again.

In a more conventional cascade such as in vertebrate rods, it is important that each and every stage of the transduction cascade is terminated rapidly, with the slowest step limiting the overall kinetics (see Phototransduction in Rods and Cones). However, a strictly localized refractory period can in principle mask the effect of any moderately slow termination reactions, as long as they are completed within the refractory period. This means that the off-response kinetics at the level of the electrophysiological response can be determined by very fast Ca^{2+}-dependent channel inactivation (time constant of <10 ms), whilst other steps such as metarhodopsin–arrestin binding, GTPase activity of the G protein and PIP_2 resynthesis could in principle afford to proceed more slowly, for example, 50–100 ms. Such a strategy could also reduce transducer noise associated with slower termination steps, which may be slow because of biophysical constraints, for example, slow binding or enzymatic reactions.

1.05.8.5 Adaptation

The microvillar design is also central to light adaptation, and in particular the ability of invertebrate photoreceptors to respond over the entire range of environmental intensities. With a refractory period of 100 ms (and probably less when light adapted), each individual microvillus should be able to generate quantum bumps at a rate of $\geq 10\,s^{-1}$. With ~45 000 microvilli in *Drosophila*, and more in the larger flies, this should allow the photoreceptors to process photon absorptions approaching $10^6\,s^{-1}$ – precisely the sorts of levels experienced under bright daylight conditions. This alone is not enough however, and to sustain such large photon fluxes without saturation, the light response needs to adapt by reducing gain. As in virtually all photoreceptors, this is achieved in the first instance by negative feedback regulation mediated primarily by Ca^{2+}, resulting in a progressive shifting of the intensity-response function curve, optimizing the dynamic range around the prevailing background light intensity. Early shot noise analysis in the 1970s and 1980s indicated that discrete quantum bumps continue to underlie the macroscopic response even under bright backgrounds, but that their amplitude and duration progressively decrease, giving rise to the adapting bump model of light adaptation, which still holds today (Wu, C. F. and Pak, W. L., 1978; Wong, F. *et al.*, 1980).

As discussed earlier (see Section 1.05.6.1), the microvillar design results in a distinction between

1. global steady-state Ca^{2+} levels, (~150 nm in the dark to maximally ~10 μM in the light), that are reached throughout the cell, including the unstimulated microvilli, and
2. the rapid microvillar transients, associated with each and every quantum bump that are maximally ~1 mM during the DA quantum bump, but only ~50–100 μM during the greatly attenuated LA quantum bumps (Figure 19).

In *Drosophila*, although Ca^{2+}-dependent feedback is found at virtually all stages of the cascade, our recent studies (see Section 1.05.6.2) suggest that the dominant mechanism for gain reduction during steady-state adaptation is the Ca^{2+}-dependent inhibition of the TRP (and TRPL) channels, which are inhibited with an IC_{50} of ~1 μM over a range that closely maps onto the global steady-state range of Ca^{2+} levels experienced during light adaptation (Figure 19). Although the mechanism is not fully understood, these relatively low concentrations of Ca^{2+} reduce the gain and shorten the duration of the quantum bump sufficiently to account for the major features of light adaptation, including the parallel shift of the response intensity function. By contrast, upstream activity of PLC appears not to be affected by these relatively low global Ca^{2+} levels, but importantly, it is inhibited over the range experienced during the rapid Ca^{2+} transients (Figure 19, Gu, Y. *et al.*, 2005).

This bipartite strategy (Ca^{2+}-dependent inhibition of channels by low global Ca^{2+} levels, and inhibition of upstream components such as PLC and M by rapid transients) can be seen as an effective solution for light adaptation, allowing for rapid response kinetics without exhausting the finite supply of PIP_2 required for phototransduction. Bump latency is a major determinant of response kinetics, and is itself critically dependent upon PIP_2 hydrolysis to generate sufficient lipid messenger to

overcome threshold for channel activation. Hence it is presumably important to maintain high PLC activity during light adaptation so as not to compromise latency. However, as shown by measurements with Kir2.1 PIP_2 biosensors (Figures 14 and 20), the rate of light-induced PLC activity in the microvilli is so high that it is sufficient to deplete the entire microvillus of PIP_2 in less than 1 s. The solution therefore is to rapidly terminate PLC activity by Ca^{2+} influx, but only after the bump has been initiated. The collapse of the light response due to exhaustion of PIP_2 in the *trp* mutant, or in Ca^{2+}-free bath, shows the disastrous consequences when this Ca^{2+}- (and PKC)-dependent inhibition fails (Figure 20).

Whilst accounting for many of the major features of light adaptation, this overview of adaptation is clearly an oversimplification. The overall output of the cell during adaptation is also influenced by many other factors, working on a variety of timescales. In particular, the description above has considered only the voltage-clamped LIC. In the physiologically relevant voltage domain, gain and kinetics will be further moderated by the passive and active (mainly voltage-dependent K^+ channels) properties of the membrane (Section 1.05.3.3); by the voltage-dependent Mg^{2+} block of the TRP channels, which reduces the effective single-channel conductance at depolarized membrane potentials (Section 1.05.4.6.2) and by synaptic feedback from higher-order interneurons (Zheng, L. *et al.*, 2006). As described in Section 1.05.2 every photoreceptor also has an autonomous pupil mechanism, whereby tiny pigment granules migrating toward the rhabdomere can reduce the effective light flux by up to two orders of magnitude. Photoreceptors in white-eyed mutants lacking this pupil saturate under bright illumination, indicating that this is an essential mechanism to avoid saturation under the brightest daylight intensities (Howard, J. *et al.*, 1987). Finally translocation of transduction components like G proteins (Section 1.05.4.4.2), TRPL channels (Section 1.05.4.6.4), and arrestin (Section 1.05.4.3.2), can fine-tune the gain and sensitivity during long-term adaptation.

1.05.9 Phototransduction Mechanisms in Other Invertebrates

1.05.9.1 Other Arthropods

It seems likely that all arthropod photoreceptors respond to light using a G_q-/PLC-based cascade resulting in a membrane depolarization. However, detailed information is restricted to relatively few preparations (notably *Limulus*, honeybee, crayfish, barnacle, and locust). Before the advent of molecular approaches, *Limulus* had been most extensively studied, and was the preferred preparation because of the large photoreceptors in the ventral eye, which allow stable intracellular recordings, and simultaneous impalement with several electrodes.

1.05.9.1.1 Limulus

In *Limulus* ventral photoreceptors, the role of $InsP_3$ as a messenger of excitation is well established. Injections of $InsP_3$ and Ca^{2+} itself both mimic the response to light (Brown, J. *et al.*, 1984; Fein, A. *et al.*, 1984; Bolsover, S. and Brown, J., 1985; Payne, R. *et al.*, 1986) and it is clear that $InsP_3$ activates $InsP_3$ receptors on the SMC, resulting in release of Ca^{2+} from intracellular stores which can raise free cytosolic Ca^{2+} to ~150 μM (Payne, R. *et al.*, 1986; Ukhanov, K. and Payne, R., 1995; Nasi, E. *et al.*, 2000). Despite compelling evidence for $InsP_3$ and Ca^{2+} as messengers of excitation in *Limulus*, the only substance that has been found to activate channels in excised patches from the microvillar membrane is cGMP (Bacigalupo, J. *et al.*, 1991). This has led to the proposal that generation of cGMP by a Ca^{2+}-dependent guanylate cyclase represents the final enzymatic component of the transduction cascade (Shin, J. *et al.*, 1993). Although there is no direct biochemical or molecular evidence for the presence of this enzyme, inhibitors of particulate guanylate cyclase severely attenuate the response to light (Garger, A. *et al.*, 2001), and a cGMP-gated ion channel has also recently been cloned from *Limulus*, which immunolocalizes to the microvillar membrane (Chen, F. H. *et al.*, 2001).

It has been suggested that this sequence of events accounts for the entire light response (Shin, J. *et al.*, 1993); however, a number of studies have reported that there may be three distinct classes of light-sensitive channels in *Limulus* (reviewed in: Nagy, K., 1991; Dorlochter, M. and Stieve, H., 1997; Nasi, E. *et al.*, 2000). These may correspond to three kinetic components of the light response that can be revealed by their differential recovery from light adaptation and distinct pharmacologies (Deckert, A. *et al.*, 1992; Nagy, K. *et al.*, 1993; Contzen, K. and Nagy, K., 1995; Nagy, K. and Contzen, K., 1997). This led to the suggestion that there may be parallel pathways involving three distinct G proteins, one operating via PLC and $InsP_3$, one via a guanylate cyclase, and one via adenylate cyclase (Dorlochter, M. and Stieve, H., 1997).

In an intriguing recent development, a *Limulus trp* homologue was cloned and found to be expressed in the ventral photoreceptors. Furthermore, the same authors found that a DAG analogue injected into the photoreceptors activate an inward current synergistically with Ca^{2+}, with electrical characteristics similar to the light-activated current (Bandyopadhyay, B. C. and Payne, R., 2004). This raises the possibility that at least one component of phototransduction in *Limulus* may be similar to *Drosophila*; i.e., a DAG-activated TRP channel. *Limulus* differs from *Drosophila* in that the light-induced current is essentially impermeable to Ca^{2+}, and therefore, the Ca^{2+}-dependent facilitation is provided by $InsP_3$-induced Ca^{2+} release, instead of Ca^{2+} influx as is the case in *Drosophila* (reviewed in Nasi, E. *et al.*, 2000).

Interestingly, quantum bumps in *Limulus* share many common features with those in *Drosophila*, including variable latency, low first stage (R-G) gain (Kirkwood, A. *et al.*, 1989), threshold, and positive and negative feedback by Ca^{2+}. However, there are also significant differences; firstly, the bump is mediated by several thousand channels spread over dozens of microvilli resulting in quantum bumps up to 4 nA in amplitude; secondly the Ca^{2+} originates primarily from Ca^{2+} release rather than influx. We can thus imagine that in *Limulus* the $InsP_3$ generated, initially in one microvillus, diffuses to the base of the microvillus where it releases Ca^{2+} from $InsP_3$-sensitive stores with sequential positive and negative feedback, probably being mediated by the bell-shaped Ca^{2+} sensitivity of the $InsP_3R$ (Payne, R. *et al.*, 1990). This results in a large, rapid, and relatively localized Ca^{2+} release signal, which can activate (possibly via GC) or facilitate ion channels over microvilli up to $\sim$2 μM distant from the release site.

1.05.9.1.2 Bee and crayfish

Bee photoreceptors have conspicuous and extensive SMC, which have functional $InsP_3$ receptors and also ryanodine receptors, which have been characterized in elegant studies using a permeabilized slice preparation (Baumann, O. and Walz, B., 1989; Walz, B. *et al.*, 1995). Whilst $InsP_3$-induced Ca^{2+} release almost certainly plays an important role in the bee, it is unknown whether the released Ca^{2+} is required for excitation or plays only roles in facilitation and adaptation, similar to the roles of Ca^{2+} influx in *Drosophila*. The large rhabdomeres in crayfish have been exploited for spectroscopic and biochemical measurements, but whilst it is clear that they have a G_q protein and PLC (Terakita, A. *et al.*, 1993) there is little data on downstream pathways. Intriguingly though, a recent report has detected PUFA production in crayfish eyes following long exposure to light, putatively via phospholipase A2 (Kashiwagi, T. *et al.*, 2000), which would release PUFAs from phosphatidylcholine. Apart from the evidence from *Limulus* there is very little evidence to suggest that cGMP plays a role in excitation in other arthropods.

1.05.9.2 Mollusks

Some of the most detailed biochemical characterizations of phototransduction in any microvillar photoreceptors have been performed in cephalopods such as the squid. Their large eyes, combined with a distinctive photoreceptor ultrastructure, whereby the microvillar membrane is separated from the rest of the cell, allows the isolation of large amounts of photoreceptive membrane in similar quantities to that available from mammalian preparations. Hence it was possible for example to extract and characterize squid rhodopsin some 50 years ago (Hubbard, R. and St. George, R. C. C., 1958). More recently, several groups have exploited this material to purify, characterize, and eventually clone and sequence several components of the cascade, including rhodopsin, G_q and PLCβ, along with a TRP homologue (Monk, P. D. *et al.*, 1996; Lott, J. S. *et al.*, 1999), which is likely to represent a light-sensitive channel. Quantitative biochemical experiments have demonstrated light-activated PLC activity (Szuts, E. Z., 1993); however, there is little or no indication as to whether $InsP_3$ or DAG (or indeed PIP_2) is the active messenger of excitation. The status and role of Ca^{2+} stores is also not clear, although (Walrond, J. P. and Szuts, E. Z., 1992) reported a system of submicrovillar tubules, which they suggested might be the equivalent of the SMC and function as Ca^{2+} stores.

Unfortunately, cephalopod photoreceptors have proved a difficult preparation for electrophysiology (but see Nasi, E. and Gomez, M. d. P., 1992) and the most detailed physiological studies of transduction in mollusks come from the scallops, *Pecten* and *Lima*. Remarkably, these bivalve mollusks have two distinct retinae with different types of photoreceptor: the proximal retina contains depolarizing microvillar photoreceptors, whilst the distal retina contains ciliary photoreceptors, which hyperpolarize. In keeping with the proposal that ciliary photoreceptors use cyclic nucleotide signaling pathways, the

light-sensitive channels in ciliary photoreceptors of the distal retina are cGMP-gated K^+ channels, and are probably activated by a cascade involving a G_o subclass of G protein and guanylate cyclase (Gomez, M. d. P. and Nasi, E., 1995; 2000). Uniquely amongst known photoreceptors, adaptation in these cells appears to be independent of Ca^{2+}, with sensitivity and kinetics of response completely unaffected by intracellular perfusion of 10 mM BAPTA (Gomez, M. d. P. and Nasi, E., 1997).

As in other microvillar photoreceptors, phototransduction in the proximal photoreceptors of *Lima* and *Pecten* is mediated by a PLC-based pathway, but once again the final mechanism of excitation is unclear (Nasi, E. *et al.*, 2000). There is clear evidence for light-induced release of Ca^{2+} from internal stores – presumably via $InsP_3$ – and $InsP_3$ injections have been reported to activate inward currents (Gomez, M. d. P. and Nasi, E., 1998). Since the light-sensitive channels (of which there are at least two classes) have only very limited permeability to Ca^{2+} (Gomez, M. d. P. and Nasi, E., 1996), the $InsP_3$ induced Ca^{2+} release is probably the major source of Ca^{2+} – whether it be for excitation, facilitation, or adaptation. In addition, DAG surrogates (phorbol esters), possibly acting via PKC, have also been reported to activate the light-sensitive channels (Gomez, M. d. P. and Nasi, E., 1998), whilst the most recent evidence has also suggested a direct role for PIP_2 depletion (Nasi, E. *et al.*, 2000; del Pilar Gomez, M. and Nasi, E., 2005).

1.05.9.3 Annelids

Leech photoreceptors, have a highly developed and extensive system of SMC, which have been shown to represent $InsP_3$-sensitive Ca^{2+} stores (Ukhanov, K. *et al.*, 2001). The photoreceptors have an unusual structure in which the microvilli enclose a large extracellular vacuole. This has been exploited by the development of a unique preparation of an inside-out cell, whereby the plasma membrane (but not the microvilli) is permeabilized, allowing unhindered intracellular perfusion of pharmacological agents, whilst an electrode can be inserted into the central vacuole to record conductance changes in the microvillar membrane. Using this preparation, it has been shown that Ca^{2+} can activate a depolarizing conductance with an EC_{50} of $\sim$1 μM. Agents that block $InsP_3$-induced Ca^{2+} release (such as heparin) block the plateau response to light, although a transient component appears relatively resistant to such agents (Walz, B. *et al.*, 2003).

1.05.10 Conclusion

Both vertebrate and invertebrate photoreceptors have been excellent models for our understanding of G-protein-coupled signaling. The bovine ROS preparation, in particular, was instrumental in the molecular identification of most of the key components of G protein-coupled signaling (see Phototransduction in Rods and Cones). *Drosophila* has been particularly important as a genetic model for PLC-based signaling, arguably the most widespread of the G-protein-coupled signaling cascades. The discovery of the TRP ion channel family was undoubtedly the most influential example of a novel signaling molecule discovered in this system, though others such as the RDGB family of PI transfer proteins, the NINAC class III myosin and the INAD scaffolding molecule also deserve mention. More than any other signal transduction cascade, phototransduction also lends itself to the most rigorous quantitative analysis, exemplified by the ability to analyze the responses to single photons. As such, the present detailed quantitative understanding of the molecular events underlying the photoresponse is unparalleled in other cellular signaling cascades.

Phototransduction in flies is often cited as the fastest known G-protein-coupled signaling cascade, and in the light-adapted state, some of the more rapidly flying Diptera can follow flickering stimuli at up to 300 Hz with 3 dB cutoffs greater than 100 Hz (Weckström, M. *et al.*, 1991). Remarkably, the same photoreceptors that sustain this performance under bright sunlight can still respond sensitively and rapidly to single photons in the dark. This is in marked contrast to vertebrates, which deploy two classes of photoreceptors to cover this range. Over 30 years of investigation, particularly in *Drosophila*, have now provided many of the answers as to how this performance is achieved. The key appears to be the extreme compartmentalization provided by the microvilli and possibly the INAD signaling complex. This minimizes diffusional delays, whilst allowing extremely rapid and highly localized Ca^{2+} transients, which accelerate the kinetics by sequential positive and negative feedback. There are nevertheless still important unanswered questions, the most pressing of which perhaps, are the exact mechanism of gating of the TRP channel, and how the dramatic facilitation by Ca^{2+} is achieved.

Although dipteran photoreceptors appear to outperform their vertebrate counterparts, their strategy

is not without costs. The main metabolic demand on any neuron is reestablishing the ionic gradients, which are required for electrical signaling and dissipated by every channel opening. The maximum potential LIC in *Drosophila* is probably in excess of 100 nA, and although this is never realized due to Ca^{2+}-dependent inhibition, peak responses of many tens of nanoamperes can be measured, and the steady-state voltage-clamped current during maintained illumination is ~500 pA. This contrasts with currents in vertebrate rods and cones, which are maximally only ~20–50 pA in the dark, and only progressively reduce during light.

Finally, although not comprehensively covered in this chapter, it has long been apparent that mutations in virtually any component of the cascade in *Drosophila* can result in retinal degeneration. In many, though by no means all cases, disturbances in Ca^{2+} homeostasis appear to be the underlying cause. Despite their distant evolutionary histories, the equivalent mutations in vertebrates also often result in hereditary retinal disease, or degenerative diseases in other systems. It is even possible to mimic a variety of human neurodegenerative diseases in the *Drosophila* eye, including Huntington's and Parkinson's disease by overexpressing the relevant mutant protein. Not only has the molecular genetic potential of *Drosophila* been decisive in enabling the analysis of the phototransduction cascade, but also similar strategies, such as genome saturating mutagenesis, can be applied to pursue the underlying molecular etiology of some of these devastating diseases (Bonini, N. M. and Fortini, M. E., 2003; Michno, K. *et al.*, 2005; Sang, T. K. and Jackson, G. R., 2005).

1.06.1 Introduction

1.06.1.1 Why Study Invertebrate Vision?

Invertebrates, in particular arthropods, have proven to be excellent model systems when it comes to studying visual information processing. This is because most arthropods show a behavioral repertoire that is mostly concerned with feeding, mating, and stability reflexes. At first glance this sounds rather boring, even though the motor tasks involved are in some cases performed at a level of speed and perfection beyond that of any vertebrate or manmade device. We will also see that some insects solve categorization and learning tasks that are complex enough for us to assume that these creatures possess cognitive capabilities. But still, why are invertebrates so successful in modern neuroscience even though their brains consist of only a tiny number of nerve cells compared to the number of nerve cells living in our own brain. The secret lies in the combination of a rigorous input–output analysis to assess the system's behavioral performance limit and a functional characterization of those identified cells and circuits underlying the studied behavior. The possibility to directly relate behavioral performance to neural activity facilitates finding conclusive answers to the question of how a given nervous system is functionally organized. Many fundamental principles in neuroscience, which turned out to apply across phyla, were actually first discovered in invertebrate model systems such as squid (e.g., Hodgkin, A. L. and Huxley, A. F. 1952), snail (e.g., Sweat, J. D and Kandel, E. R., 1989), horseshoe crab (e.g. Hartline, H. K. *et al.*, 1956), and beetle (Hassenstein, B. and Reichardt, W., 1953).

1.06.1.2 The Closed Loop of Action and Perception

The different processes taking place in the nervous system which underlie the control of behavior may be illustrated in an action–perception loop (Figure 1). Adaptive behavior relies on constantly sampling information from the environment. This is essential as behavior is always generated in relation to a given internal and environmental state. Therefore, successful behavioral control requires to identify and to distinguish between two different sources of information: First, information about the environment caused by external sources, for instance other animals. Second – when being active – information about how the animal is moving relative to its environment. Both aspects of information become the basis of any behavioral response, and as a long-range sense, vision plays a major role in it.

In invertebrates, arrays of thousands of specialized photoreceptor cells transduce local changes of photon flux into time-varying receptor signals. An account on the significance of the optics and the latest development in invertebrate phototransduction (Chapter Phototransduction in Microvillar Photoreceptors of Drosophila and Other Invertebrates) is given in earlier chapters. At the peripheral level the arrangement and functional structure of receptor cells already reflects on what the visual input to different regions of the eye might be used for in the context of behavioral control (Chapter Nocturnal Vision; Hardie, R. C. 1983; Stavenga, D. G. 1992). The next step is devoted to sensory processing mostly concerned with filtering,

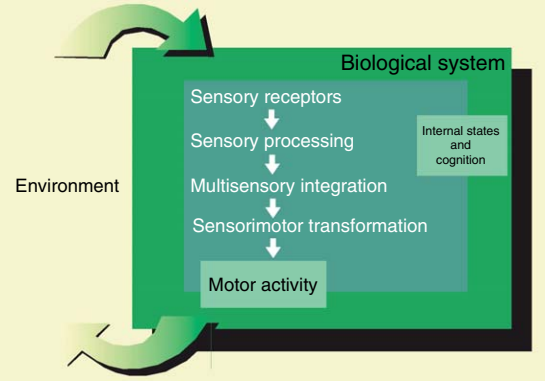

Figure 1 The action–perception loop. A bilogical system receives processes, and integrates sensory information before transforming the resulting signals into activity patterns controlling the motor system. Motor activity produces a behavior that changes the sensory environment, which is again sampled by the sensory receptors. The different steps of this action–perception loop may be modified depending on internal states or by higher cognitive functions. Such modifications may result in different behavioral patterns in response to one and the same sensory environment. Feedback loops may also be implemented at different levels to fine-tune the behavior.

refining, and encoding particular aspects of local sensory information. This step may be facilitated by taking into account internal models, or prior knowledge, of natural image statistics (van der Schaaf, A. and van Hateren, J. H., 1996) to optimize the extraction of behaviorally relevant information (Chapters Visual Ecology and Seeing in the Dark: Retinal Processing and Absolute Visual Threshold; Laughlin, S. B., 1981). In functional terms, the peripheral and the later central processing have fundamentally different purposes. Peripherally, it is important to gain detailed information about intensity and color distributions for each tiny patch of the visual scenery. It is like taking a photograph with a digital camera: bad optics in combination with low pixel resolution will not give you particularly good result. Similarly, whatever information visual systems loose in the periphery will never be retrieved at downstream stages.

A local sensory signal, equivalent to the color and the intensity of a single static pixel in a photograph, does not provide the animal with any evidence about its current behavioral state, whatsoever. Local signals are highly ambiguous since they lack any contextual information – unless they are meaningfully combined (e.g., Laughlin, S. B., 1999). Consequently, evidence of being in a state that requires a particular behavioral response is gained only by selective integration of local sensory signals. This task is commonly performed by populations of interneurons within each modality. In fact, in many modalities, different qualities, such as color or motion information in case of vision, may be processed and integrated in parallel anatomical pathways (see Section 1.06.2). The results are then combined with information from other senses to further increase the certainty of being in a distinct behavioral state. The final outcome of such multisensory integration is then transformed into activation patterns of motorneurons driving the muscles, which ultimately control the behavior.

Any behavioral response and its underlying neural processing take place under closed-loop conditions. Whilst executed, behavioral actions usually result in a continuously changing pattern of sensory inputs, which closes the action–perception loop. However, the sensory input does not entirely determine the behavioral output. Physiological parameters such as nutritional state and temperature may modify the operation of the nervous system at various levels so that one and the same sensory input pattern can result in different behavioral outputs. For instance, a hungry fly may land and search for food when it encounters a visual expansion pattern that indicates an approaching obstacle. Well-fed flies experiencing the very same pattern, on the other hand, may just fly past the obstacle to avoid collision (e.g., Srinivasan, M. V. and Zhang, S. W., 2000). This means that the neural machinery controlling the behavior does not entirely work in a deterministic way but may as well show a certain degree of context-dependent plasticity (e.g., Wolf, R. *et al.*, 1992; Heisenberg, M. and Wolf, R., 1993).

1.06.1.3 Visually Induced Reflexes and Voluntary Movements: Inner-Loop and Outer-Loop Control

In invertebrates, vision is involved in the control of several behaviors, which may be supported by differently organized neuronal pathways (e.g., rev.: Wehner, R., 1981). Flying insects in particular, not being able to use short-range senses such as touch and taste when airborne, heavily rely on vision in a variety of behavioral contexts. Vision is the key sense to identify and chase potential prey or mates, to detect, approach, and land on potential food sources in close range, to avoid collisions with obstacles in the environment, and for initiating escape responses. Insects also use visual information for estimating distance flown and navigation. Finally, invertebrates

generally use visual information to support two fundamental tasks: gaze and flight stabilization.

Gaze and flight stabilization should be distinguished from other visually guided behaviors since both operate very much like reflexes. The visually induced components of these reflexes are often referred to as optomotor responses (e.g., rev.: Heisenberg, M. and Wolf, R., 1993). But gaze and flight stabilization are under multimodal control. In Diptera – or two-winged flies – these reflexes depend, for instance, on the mechanosensory haltere system also (e.g., Nalbach, G., 1994; Sherman, A. and Dickinson, M. H., 2003; Bender, J. A. and Dickinson, M. H., 2006). The visual and mechanosensory components of gaze and flight control in insects are analog to the vestibulo-ocular, optokinetic, and postural reflexes in humans (rev.: Carpenter, R. H. S., 1988; Miles, F. A. and Wallman, J., 1993; Sparks, D. L., 2002). Across phyla they serve two essential functions: Postural control helps to maintain a stable attitude during locomotion – be it flying, swimming, or waking (rev.: Orlovsky, G. *et al.*, 1999). The stabilization of gaze keeps the retinal image in its default upright orientation, which is a necessary prerequisite for processing visual information, and simplifies the sensorimotor transformation (Miles, F. A. and Wallman, J., 1993).

In engineering terms, gaze and flight stabilization are governed by an inner-loop control system that is constantly in operation (Figure 2, dashed red line). No matter whether an insect chases another, performs a collision-avoidance maneuver, or is in cruising flight mode, gaze and flight need to be stabilized. For instance, when a gust of wind drifts a fly off course the optomotor response kicks in to support two fundamental tasks: (1) to maintain aerodynamic stability and (2) to compensate for the animal's deviation from its initial flight trajectory. This causes an interesting problem, which has been raised almost 60 years ago by von Holst E. and Mittelstaedt H. (1950). The control of visual reflexes and other visually guided behaviors has to interact, otherwise the animal would be trapped by its inner-loop control system (von Holst, E. and Mittelstaedt, H., 1950). What happens when the animal intends to fly a banked turn so that it can reach, say, an attractive landing site? As soon as the maneuver starts the inner-loop control should counteract the voluntary turn and the animal would never be able to reach the desired target location. The observation is, however, that insects have no problem at all to engage in maneuvers whose execution should be opposed by the optomotor reflexes (e.g.: Collett, T. S., 1980; Heisenberg, M. and Wolf, R., 1993).

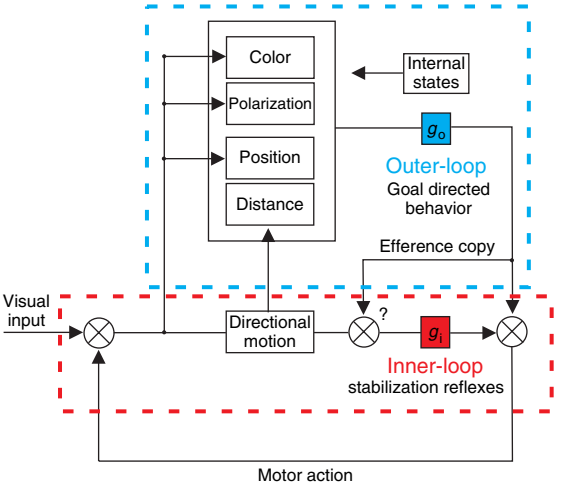

Figure 2 Inner-loop and outer-loop control. Inner-loop stabilization reflexes help an animal to keep its balance, or aerodynamic stability, and to maintain a default orientation of its eyes relative to the external world. Visual motion in particular is used in inner-loop control (dashed red frame). To perform any goal-directed behavior the inner-loop control has to be modified. Otherwise, inner-loop reflexes would immediately oppose voluntary action. Along the outer-loop (dashed blue frame) separate parallel pathways process and integrate different qualities of vision. Internal states of the animal may have an impact on outer-loop integration. The resulting signals are fed into the inner-loop control to modify its performance. If outer-loop and inner-loop dynamics greatly differ, the interaction between the loops would benefit from including an efference copy, which subtracts the expected consequences of any outer-loop action. At which stage, efference copy might effect the inner loop is not clear yet. g_i and g_o denote inner- and outer-loop gain. For further explanation see text. Inspired by Collett T. (1980).

Conceptually, this problem can be solved in two different ways either by disabling the reflex or by modifying its execution. The first solution could be the result of several, not necessarily mutually exclusive mechanisms. For instance, voluntary turns may be executed at such high speeds that the resulting retinal image velocities exceed the dynamic range of the motion vision system (rev.: Heisenberg, M. and Wolf, R., 1993). In this case a low gain in the optomotor response would simply be an inevitable consequence of the visual system's intrinsic properties. Classical reflex theory (e.g., Fulton, J. F., 1943) suggests another possible solution. Early hypotheses assumed that the visual processing of motion information or the resulting motor command may be inhibited whenever voluntary turns are performed.

These possibilities, though, had to be discarded after von Host E. and Mittelstaedt H. (1950) performed their classic experiments on the hoverfly showing that this is clearly not the case.

The second conceptual solution is reminiscent of the design of control systems in modern aircrafts. Like in flying insects an inner-loop control system that does not require pilot action is constantly maintaining the aircraft's attitude in conjunction with its aerodynamic stability by compensating for any deviations in roll, pitch, and yaw. During a voluntary banked turn the pilot due to joystick action simply changes the set point of the inner-loop control system. Such outer-loop control allows the pilot to perform intended flight maneuvers while keeping the inner-loop control active. In insects where there is no pilot the outer-loop control may be based on pathways processing, for instance, the retinal position of potential targets, information required during chasing flights.

The latter possibility was discussed as a follow-up model, one out of three possible ways of how the inner-loop optomotor pathway and an outer-loop pathway involved in chasing behavior may interact (Collett, T. S., 1980). Another possible interaction Collett T. S. (1980) put forward requires a copy of the motor command sent to the flight motor called an efference copy – an idea von Holst E. and Mittelstaedt H. introduced in their 1950 publication. An efference copy is a signal of the same amplitude but inverted in sign with respect to the reafferent sensory feedback that an animal's – or human's – own motor activity will cause. Voluntary movements during chasing could trigger an efference copy that cancels the visual feedback due to the animal's voluntary turns so that the inner-loop control will not generate an opposing optomotor response (Figure 2, blue dashed line).

Because an efference copy in a way predicts what the self-induced sensory feedback will be, it is conceptually similar to what is known as a forward model in human motor control. Any difference between the predicted feedback, the forward model, and the actual feedback may have two different reasons: Firstly, the mismatch was due to external factors in which case further correctional movements are required. Secondly, the motor program was not appropriately trained to achieve the goal. In the latter case the difference between actual feedback and forward model may be used to train the motor program for better future performance. In vertebrate motor control, forward models became quite popular as a concept (e.g., Wolpert, D. M. *et al.*, 1995) and were even associated with cognitive processes (Kawato, M., 1999; Wolpert, D. M. and Ghahramani, Z., 2000). The neural basis of forward models, however, has so far only been shown in a cerebellum-like area of the electric fish brain (rev.: Bell, C. C., 1989).

At which stage in the insect nervous system and how forward models or efferent copies modify visual information processing and the resulting motor output is not very well known yet either (Webb, B., 2004). Only in the context of gaze stabilization in locusts (Zaretsky, M. and Rowell, C. H., 1979) and attitude control in flies (Chan, W. P. *et al.*, 1998) some electrophysiological evidence hints at how the inner- and outer-loop control might interact.

1.06.1.4 Goal of this Chapter

The goal of this chapter is to complement the comprehensive account *Spatial Vision in Arthorpods* provided by Wehner R. (1981) in the *Handbook of Sensory Physiology*. We will confine ourselves to review a selection of examples where over the last decades an integrated approach of quantitative behavioral studies in combination with electrophysiology and modeling best illustrates neural mechanisms underlying visually guided behavior. Many of these studies have been successfully carried out in a variety of flying insects, namely flies. In Section 1.06.2, therefore, we will consider the general organization of the insect nervous system before outlining the control of behaviors involving vision – and, in some cases, other sensory mechanisms.

1.06.2 Anatomy and Morphology of the Insect Brain

1.06.2.1 General Organization

Here we will just give a short description of the neuronal organization of the insect brain to help readers of this chapter unfamiliar with insect brain anatomy to orient themselves with respect to structures and neurons discussed in more detail below. Detailed accounts on the anatomy and the structure of the optic lobes can be found in Strausfeld N. J. (1976; 1989) and Fischbach H. and Dittrich A. P. M. (1989). Strausfeld concentrates mainly on the housefly but also includes many other insects and invertebrates, whereas Fischbach and Dittrich focus only on *Drosophila*. There are also several detailed and interactive brain atlases available on the web (e.g., honeybee: http://www.neurobiologie.fu-berlin.de/

beebrain/; diptera: http://flybrain.neurobio.arizona.edu/). Here we concentrate mainly on the insect brain in which the general structure of the brain and optic lobes is conserved over different species.

The neural organization of the insect brain combines two design principles: single, identifiable neurons and multiple neurons arranged in a parallel architecture. The first principle is based on the existence of single neurons that are individually identifiable functional elements in sensory–motor routines and can be repeatedly and reliably identified due to their unique morphology and physiology. The H1 cell, for instance, that is found in the lobula plate of flies would be a famous example (see Section 1.06.3.1.3). Such identified neurons are characteristic of the invertebrate nervous system. Multiple neurons in a parallel architecture indicating higher-order integration are represented, for example, in the mushroom bodies (MBs). The MBs are central, prominent structures consisting of small, tightly packed, and parallelly arranged neurons called Kenyon cells.

In insects the nervous system is divided into a cephalic ganglion (brain), thoracic and abdominal ganglia, which may be fused. These ganglia are connected by interganglion tracts. The cephalic ganglion is the main area in which processing and integration of sensory information as well as higher-order functions such as learning and memory are performed. The thoracic ganglia contain most of the neuronal machinery responsible for the control of flight and leg muscles. All the ganglia and most notably the cephalic ganglion are subdivided into neuropil masses and connecting tracts. Most synapses and arborizations of neurons are situated in the neuropil masses. The cell bodies of the neurons are located in an outer rind that envelopes both the neuropil and the connecting tract regions. The cephalic ganglion can be easily divided into functional and anatomical distinct sensory and higher-order processing regions, with the olfactory and the optic lobes, the MBs, and central complex (CC) being prominent anatomical structures.

The visual system in insects consists of the retina and three nested optic lobe neuropils, lamina, medulla, and lobula complex. In Diptera, Lepidoptera, and Coleoptera, the lobula complex is divided into two neuropils, the lobula and the lobula plate. In all other insect groups these two neuropils are fused into the lobula or the lobula complex. Successive chiasmata link the lamina to the outer medulla and the inner medulla to the lobula complex (Figures 3 and 4).

The optic lobes of insects are retinotopically organized. The spatial relationship of information obtained

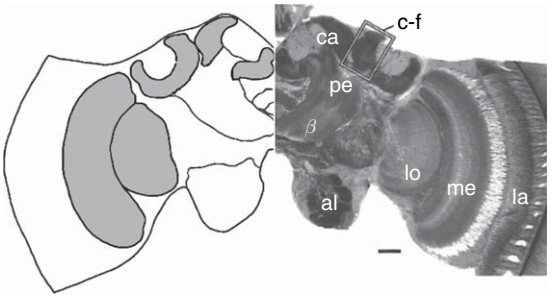

Figure 3 A frontal section of the bee brain is shown. The left side is a schematized drawing of the optic lobes and mushroom bodies (MBs), the right side shows an ethylgallate staining. Note the darker neuropil regions with clear columnar organization and the lighter colored chiasmata, fiber tracts, and cell body rind. al, antennal lobe; ca, calyx; la, lamina; lo, lobula; me, medulla; pe, peduncle; β, β-lobe of peduncle. Scale bars, 100 m. Adapted with permission from Ehmer, B. and Gronenberg, W. 2002. Segregation of visual input to the mushroom bodies in the honeybee (*Apis mellifera)*. J. Comp. Neurol. 451, 362–373.

at neighboring points in visual space is kept intact throughout processing in the optic lobes. The neuropils of the optic lobes are characterized by their columnar structure. Identical groups of cells, consisting of several different types of small-field neurons that are individually identifiable, are repeated for each visual sampling point. In the lamina these identical repeated groups of cells are called cartridges; in the medulla they are termed columns. This organization also implies that early processing of local information is repeated in each of the cartridges and columns. Preprocessing of local information is performed by different neurons or sets of neurons, which are identical in each of the columns. This columnar structure is intersected by several different planar networks of neurons, for example: (1) amacrin cells that provide local networks and (2) wide-field tangential cells that collect and process visual information from multiple columns and thus sample larger parts of the visual field. These neurons can access different types of preprocessed local information for each visual sampling point and relate it out to other visual areas in the optic lobes or central brain regions.

1.06.2.2 Lamina

The lamina, the first and the most peripheral of the three optic neuropils, receives retinotopic inputs from the retina. Each ommatidium provides receptor axons from the photoreceptors that are called short or long visual fibers depending on whether they terminate in

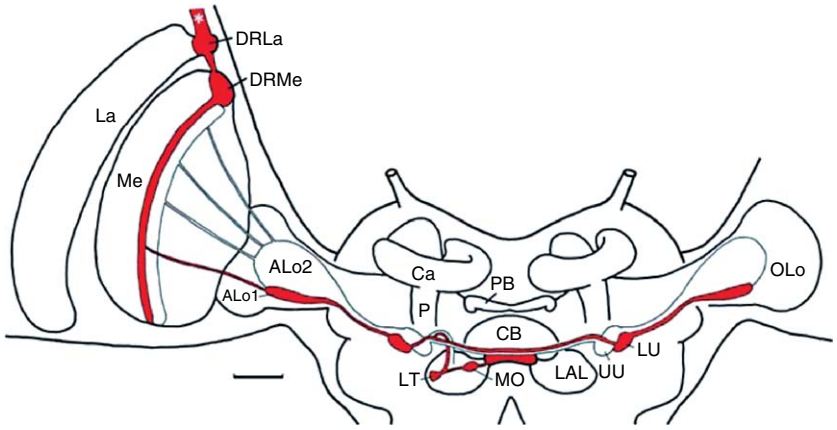

Figure 4 Schemata of the brain of the locust *Schistocerca gregaria* with its polarization vision pathways highlighted in red. ALo1-2, layers 1 and 2 of the anterior lobe of the lobula; Ca, calyces of the mushroom body (MB); CB, central body; DRLa, DRMe, dorsal rim areas in the lamina and medulla; La, lamina; LaL, lateral accessory lobe; Me, medulla; OLo, outer lobe of the lobula; P, pedunculus of the MB; PB, protocerebral bridge; UU, upper unit of the anterior optic tubercle. Organization and neural connections of the anterior optic tubercle in the brain of the locust, *Schistocerca gregaria*. J. comp. Neurol. 462, 415–30.

the lamina, short visual fibers, or in the outer medulla, long visual fibers. These axons from a single ommatidium form together with some second-order neurons a neuronal bundle, which is called a lamina cartridge. The lamina gives rise to monopolar cells. All monopolar cells from one lamina cartridge project together across the first optical chiasma into the corresponding column of the outer medulla. They are joined by the long visual fibers that pass through the same cartridge. Diptera are an exception to this type of organization. Flies possess a so-called neural supposition eye in which the R1–R6 photoreceptors (short visual fibers) of each ommatidium have different optical axis. Therefore they sample information at different points in visual space. However, six R1–R6 photoreceptors from different ommatidia share the same optical axis and thus sample the same point in space. The axons of these six photoreceptors converge onto a single optic cartridge in the lamina. Each lamina cartridge sends six neurons, five monopolar cells and one T basket cell, across the first optic chiasma to the medulla, together with the axons of R7 and R8 photoreceptors (long visual fibers) that also share the same optical alignment (Kirschfeld, K., 1967).

1.06.2.3 Medulla

The medulla is the second optical neuropil and can be divided into three regions, the outer, the inner medulla, and the serpentaine layer, which separates the outer and the inner medulla. Lamina monopolar cells and long visual fibers are the main inputs into the outer medulla. The chiasma between the lamina and the medulla is crossed but the retinotopy is conserved as mentioned above. Like the lamina, the inner and the outer medulla are characterized by a columnar structure. Several identified types of small-field neurons are repeated in each of the laminar cartridges and medullar columns. Centrifugal T cells, which are present in most species and comprise several distinct anatomical and functional subclasses, link the outer medulla to the inner medulla and the medulla to the lobula and the lobula plate. The serpentaine layer is characterized by large tangential neurons that collect and process information across several columns and project to the central brain.

1.06.2.4 Lobula Complex

The lobula plate receives retinotopic inputs from both the medulla and the lobula. The inputs are mainly small-field columnar neurons, such as various T, Tm, and Y cells from the medulla and the small-field columnar neurons, which connect the lobula with the lobula plate. The lobula plate houses large motion-sensitive tangential neurons that have been characterized both anatomically and physiologically in Diptera, Lepidoptera, and Orthoptera (see Sections 1.06.3.1 and 1.06.3.2).

The lobula in turn receives input from the medulla. The input is also retinotopic and consists mainly of small-field columnar neurons, similarly various T, Tm, and Y cells, and also receives inputs from the lobula plate via small-field columnar

neurons. The lobula consists mainly of columnar neurons, which are arranged in retinotopic arrays. Color processing seems to be one of the main features in the lobula (see Section 1.06.4.1), and neurons detecting orientations of lines have also been recorded there (see Section 1.06.3.3).

1.06.2.5 Projections to Other Parts of the Nervous System

The main output regions of the optic lobes are in the supra- and subesophageal ganglia. The dorsal protocerebrum receives terminals of neurons originating in the lobula plate. The ventrolateral protocerebrum is the main output area of the lobula. Both the dorsal and the ventrolateral protocerebra contain the dendrites of many descending neurons that connect to motor centers in the thoracic ganglion. Descending neurons are neurons that originate in the supra- or subesophageal ganglia and connect the brain to one or more thoracic and/or abdominal ganglia. Ascending neurons, on the other hand, are neurons with opposite polarity. The central body complex, the ventral or accessory lobes that are located on either side of the central body complex, and the MBs also receive input from the visual system (Figures 3 and 4).

The central complex CC is located in the center of the brain. It is a highly structured, columnar neuropil consisting of the protocerebral bridge (PB), the upper, and lower central body (CBU and CBL). The CC is connected to the motor centers in the thoracic ganglion and are thought to be involved in the spatial control of locomotion, and it might represent a general spatial organizer in the insect brain.

The MBs are paired structures located in both halves of the central brain region. They are divided into the main input region, the calyces and the peduncles, which show a highly parallel organization. They are composed of intrinsic neurons, the Kenyon cells. The MBs receive multisensory information and are thought to be important for multisensory integration, learning, and memory function. The MBs receive olfactory information through the calyces while other sensory information are received through the peduncles. Hymenoptera are an exception to this; here olfactory and visual information are received through the calyces.

1.06.2.6 Functional Anatomical Pathways

Similar to the above-mentioned principles of single individual neurons and multiple parallel neuron architecture, we can find two analog types of projection pathways. The first type supports mostly fast, reflex-like functions and comprises a single or very few neurons with just one or a few synapses between the neurons analyzing the visual input and the motor output regions.

A perfect example for a fast, small circuit pathway can be found in the locust (Section 1.06.3.2). Here the visual information that the locust uses to initiate escape or evasive flight maneuvers in response to approaching objects is processed in a lobula wide-field neuron, the lobula giant movement detector (LGMD). The output of the LGMD is transmitted to a descending neuron, the descending contralateral movement detector (DCMD), that projects to the motor centers in the thoracic ganglion. The visual information is thus transferred to motor neurons innervating leg and flight muscles. The synapse between the LGMD and the DCMD is a one to one synapse, for every spike in the LGMD a spike is generated in the DCMD, and thus there is no additional processing happening at this synapse (Section 1.06.3.2).

Projection pathways that are highly parallel and that might involve multiple synaptic transmissions between the sensor and the actor units are more indicative of higher-order integration. They are quite common in the visual system of invertebrates. Two good examples for such pathways are: (1) The polarization vision pathway. An up-to-date schemata of the understanding of this pathway is shown in Figure 4. (2) The projection of visual and chromatic information from the optic lobes to the MBs is another good example. In the medulla and the lobula of bees, several classes of color-opponent neurons have been characterized, which project through two tracts either to the MBs or to the contralateral optic lobe (see Section 1.06.4.1). These cells have receptive fields of varying size and so far no retinotopic organization has been found. Medulla and lobula outputs have been traced to the calyces, the main input area of the MBs. The outputs from the medulla comprise two different tracts, the anterior inferior and anterior superior optic tract, whereas neurons originating in the lobula use the lobula tract. All three tracts together contain roughly 400 neurons. The input into the MB calyces is not retinotopic except that it is segregated between the ventral and the dorsal halves of the visual field. Each input cell sends out multiple processes to different parts of the circumference of one of the calyces. The MBs comprise a large number, 340 000 in honeybees, of small,

parallelly arranged neurons, Kenyon cells, which originate in the calyces and run along the length of the MB peduncles. The color-sensitive medulla and lobula cells connect to these Kenyon cells. Here further processing takes place and the information is then relayed to other parts of the brain or to the thoracic ganglion and the motor output units. This example illustrates a much more complex pathway organization. Here we see a massive parallel organization of both the pre- and the postsynaptic components. Multiple synapses and multiple pre- and postsynaptic cells are involved in visual information processing and potentially in multisensory integration in the MBs. In this case lateral integration and complex processing of information might occur at each step of the pathway.

The organization of these two different pathways also highlights different principles of information processing. The LGMD integrates all these visual stimulus parameters required to sense an approaching object and, via the DCMD, transmits signals to various motor systems. Even though the DCMD also receives information from other modalities, the integrated information is used only in a specific context, evasive or escape behavior.

In contrast, the second example shows a more flexible way of visual information processing. A medulla cell can have color opponent properties. But, one color opponent cell is not sufficient for the bee to precisely identify the color of a stimulus and importantly whether this color is behaviorally relevant. The highly parallel organization of this pathway is perfectly well suited for the integration with other sensory information. Such architecture allows for a high degree of flexibility concerning further processing and motor output. Depending on the internal state of the animal, its prior experience and learning and information about the state of the world, the chromatic information may be used for widely different behavioral tasks.

1.06.3 Motion-Based Visual Information Processing

What is motion vision good for? Strictly speaking, motion, that is, relative motion between the eyes and the surroundings, is a necessary prerequisite for any visual perception. This might sound very strange but it is in fact just the consequence of the way photoreceptors work. Photoreceptors stimulated at a constant light level adapt. An image perfectly stabilized with respect to the retinal photoreceptor arrays will therefore result in the loss of any visual perception. Besides this phenomenon, there are many answers to the question, some of which are quite obvious from our everyday experience. When walking in a crowded place it is good to know whether we should better change our path to the left or to the right in order to avoid bumping into people. Or, when crossing a street knowing the direction the cars are driving in is essential for making it safely to the other side. But motion is also useful to make sense of the world in less intuitive ways. Relative motion allows visually oriented animals, including humans, to infer how far objects are away and breaks camouflage between motionless objects in front of a stationary background.

The analysis of directional motion, which is essential for the visual estimation of self-motion, is one of the most thoroughly investigated fields in insect vision. In this area, behavioral and neurophysiological experiments have been combined in a remarkably successful way. A couple of discoveries were made in this area during the past decade, which considerably improved our understanding of the neural basis of visually guided behavior. Comprehensive accounts on the computational aspects of vision, in general, may be found in some more specialized textbooks (e.g., Mallot, H. A., 2000).

1.06.3.1 Estimating Self-Motion Using Directional Motion Cues

Visual estimation of self-motion is a necessary requirement for an inner-loop control system to function. In this section we will focus on the significance of processing directional motion in the context of gaze and flight stabilization. At the end of this section we will also review recent evidence that directional motion vision may also play an important role in obtaining distance information useful to avoid collisions during flight in confined areas. The latter function could be seen as a potential basis for an outer-loop interacting with the flight-stabilizing inner loop (Figure 2). Most of our knowledge about the neural processing of directional motion comes from studies on various fly species – the model systems we will be concentrating on.

1.06.3.1.1 Self-motion and optic flow

To control gaze and flight in a closed-loop situation, animals constantly acquire information about their self-motion in space. This is where directional

motion vision comes into play. While moving through an otherwise stationary environment, animals experience panoramic retinal image shifts, optic flow fields. Optic flow fields result from relative movement between objects in the environment and the eyes. The structure of optic flow fields is intimately related to the way the animal moves, which is determined by the self-motion parameters, translation and rotation. Conversely, analyzing optic flow allows the animal to assess its self-motion parameters and to use this information for control purposes.

In the 1950s, Gibson J. J. (1950; 1958) already put forward the idea that optic flow provides a rich source of self-motion and distance information. Gibson's contributions, however, stayed at a rather qualitative level. Only later, Nakayama K. and Loomis J. M. (1974) as well as Koenderink J. J. and van Doorn A. J. (1987) introduced a formal description of optic flow that is incredibly useful to quantify self-motion-generated input to the visual system. Koenderink J. J. and van Doorn A. J. (1987) worked out a theoretical framework in vector notation – often referred to as **KvD** algorithm – which helped to develop ideas of how the visual system might be able to retrieve self-motion parameters from optic flow fields. They introduced an iterative least-square algorithm to estimate the self-motion parameters, i.e., the translation vector **T** and the rotation vector **R**, which best describe a field of noisy motion parallax vectors $\mathbf{p}_i$:

$$\mathbf{p}_i = \frac{\Delta \mathbf{d}_i}{\Delta t} = -(\mathbf{T} - (\mathbf{T}\cdot\mathbf{d}_i)\mathbf{d}_i)/D_i - (\mathbf{R}\times\mathbf{d}_i) \qquad [1]$$

with each $\mathbf{p}_i$ obtained at a defined direction in space $\mathbf{d}_i$. Equation [1] shows that each $\mathbf{p}_i$ is given by the linear sum of the translation- and rotation-induced contributions. It also shows that the translation-induced component depend not only on the magnitude of **T** but also on the distance D_i between the visual sensor and any visible object at directions $\mathbf{d}_i$. This confounding effect of distance and translational velocity causes a problem: Moving slowly past an object at close distance results in the same contribution to a given $\mathbf{p}_i$ as moving quickly past an object that is further away. There is no hope of recovering the actual translation vector **T** unless the distance D_i was explicitly known for each $\mathbf{d}_i$ and/or there was knowledge about the speed of translation $|\mathbf{T}|$.

Since this is usually not the case, Koenderink J. J. and van Doorn A. J. (1987) introduced the reduced nearness, $\mu_i = |\mathbf{T}|/D_i$, which allows for arbitrary combinations of speed and local distance resulting in the same reduced nearness. By doing so the **KvD** is confined to retrieve only the direction of translation **t** rather than both its direction and magnitude given by **T**. Taking this modification into account, eqn [1] can be rewritten as follows:

$$\mathbf{p}_i = -\mu_i(\mathbf{t} - (\mathbf{t}\cdot\mathbf{d}_i)\mathbf{d}_i) - (\mathbf{R}\times\mathbf{d}_i) \qquad [1a]$$

This equation provides the basis for a set of three coupled linear equations (Koenderink, J. J. and van Doorn, A. J. 1987) to obtain estimates of $\mathbf{R}'$, $\mathbf{t}'$, and $\boldsymbol{\mu}_i'$, Which produce estimates of the local parallax vectors $\mathbf{p}_i'$. The system then iterates the parameters to minimize the least-square error E between the measured and estimated local parallax vector.

$$E = <|| \mathbf{p}_i - \mathbf{p}_{i'} ||^2> = 0$$

where rectangular brackets denote the average across all n available directions $\mathbf{d}_i$. The iterative **KvD** algorithm theoretically requires only five directions at which local parallax vectors are measured to produce an estimate of the self-motion parameters. More directions increase the reliability with which the parameters can be estimated when applying the algorithm repetitively to noisy optic flow fields (Koenderink, J. J. and van Doorn, A. J., 1987). In that respect, insects such as fruitflies with 800 ommatidia per eye and dragonflies with nearly 30 000 ommatidia per eye (e.g., Land, M. F. and Nilsson, D. E., 2002) involved in estimating local motion direction are rather well equipped to solve the task. The short behavioral response time to visual stimuli, however, does not speak in favor of them applying an iterative algorithm to estimate self-motion. Therefore, based on the **KvD**, a one-shot estimator of self-motion parameters was proposed (Dahmen, H. *et al.*, 2001), which uses the following equations to estimate **t** and **R**:

$$\mathbf{t}' = -k[\mathbf{I} - \mathbf{M}_t/n]^{-1}\left[<\mu_i'\mathbf{p}_i> + R'\times<\mu_i'\mathbf{d}_i>\right] \qquad [2]$$

$$\mathbf{R}' = [\mathbf{I} - \mathbf{M}_r/n]^{-1}\left[<\mathbf{p}_i\times\mathbf{d}_i> + (\mathbf{t}'\times<\mu_i'\mathbf{d}_i>)\right] \qquad [3]$$

where k is a normalization factor chosen to grant $|\boldsymbol{t}'| = 1$, **I** stands for the 3×3 identity matrix, while $\mathbf{M}_t$ and $\mathbf{M}_r$ are 3×3 matrices containing the average of the dyadic products $\mu_i\mathbf{d}_i \otimes \mu_i\mathbf{d}_i$ and $\mathbf{d}_i \otimes \mathbf{d}_i$, respectively. These equations illustrate an important point in the context of estimating self-motion parameters from optic flow: The estimate of $\boldsymbol{t}$ also depends on $\boldsymbol{R}$ and vice versa as stated by the right-hand terms in eqns [2] and [3]. These apparent translation and rotation terms (Koenderink, J. J. and van Doorn, A. J., 1987; Dahmen, H. *et al.*, 2001) result

from ambiguities in local measurements of directional motion. A parallax vector $\mathbf{p}_i$ measured locally could have been caused by translation or rotation (Figure 5, gray areas in (b), (c), and (d)). But eqns [2] and [3] also suggest strategies of how to reduce these terms for a more reliable estimation of self-motion parameters – which, indeed, some insect visual systems seem to have adopted (Section 1.06.3.1.3).

As mentioned in the previous section, self-motion in space can be described in terms of translations **T** and rotations **R** referring to movements along and around the cardinal body axes (Figure 5(a)). Optic flow fields induced by translation have a different

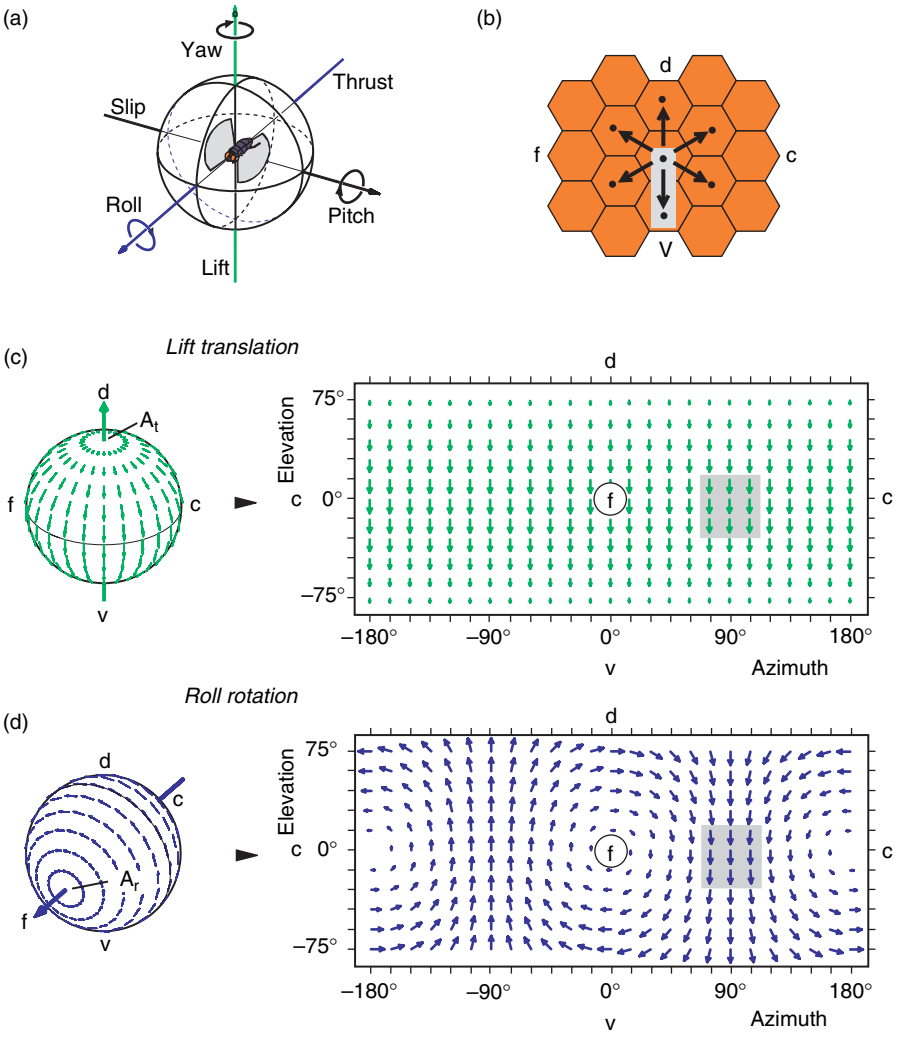

Figure 5 Self-motion and optic flow. (a) Self-motion can be described in terms of translation- and rotation-components along and around the cardinal body axes. (b) Small section of a compound eye sampling information in the lateral visual field of the right eye. In a first approximation, the direction of local retinal image shifts is analyzed along ommatidial rows within the hexagonal eye lattice (black arrows; f, frontal; c, caudal; d, dorsal; v, ventral). (c, d) Structural features of global optic flow generated during lift translation (c) and counter clockwise roll rotation (d) is presented on the surface of the visual unit sphere (left) and in a cylindrical projection (right), where *f* denotes the position directly in front of the animal. A_t in (c) and A_r in (d) indicate the axis of translation and rotation, respectively. Note the marked differences between translation- and rotation-induced optic flow at the global scale. But also note that at the local scale the direction of flow vectors is ambiguous. In the right visual field, around elevation = and azimuth = 90° (gray area), during lift translation and roll rotation, local flow vectors point in the same direction. For further explanation see text. Adapted from Krapp, H. G. and Hengstenberg, R. 1996. Estimation of self-motion by optic flow processing in single visual interneurons. Nature 384, 463–466; Krapp, H. G., Hengstenberg, B. and Hengstenberg, R. 1998. Dendritic structure and receptive-field organization of optic flow processing interneurons in the fly. J. Neurophysiol. 79, 1902–1917.

global structure than those induced by rotation. This becomes obvious when comparing optic flow fields occurring during upward movement along the vertical body axis (lift translation, Figure 5(c)) and during a rotation around the longitudinal body axis (roll rotation to the left, Figure 5(d)). Both flow fields were calculated using eqn [1a] assuming a unit distance to all objects in the visual world, which emphasizes the structural differences between rotational and translational flow fields.

The orientation and the length of each individual vector in Figures 5(c) and 5(d) indicate the direction and the relative magnitude of the retinal image shift at different positions within the spherical visual field. The positions are determined by two angles: the horizontal azimuth, φ, and the vertical elevation, θ, where azimuth = elevation = 0° defines the point directly in front of the animal (**f**, in Figures 5(c) and 5(d)). Negative and positive azimuths indicate positions in the left and the right visual hemisphere, respectively. Negative and positive elevations refer to positions below and above the horizon. Translation- and rotation-induced optic flow fields have in common that the direction of translation and the axis of rotation, respectively, define the location in the flow fields where no relative motion takes place and therefore the vectors disappear. From these flow field singularities the relative motion increases gradually and becomes maximum at the flow field equator. Two structural differences help to distinguish between translation- and rotation-induced flow fields: In a translation flow field the local velocity vectors are aligned along great circles connecting the two singularities in the field with one another. The vectors in the rotation flow field, instead, are aligned along parallel circles centered with the axis of rotation (Figure 5(c) and 5(d), spherical presentation). The second difference concerns the magnitude of local motion vectors. In translation-induced optic flow fields, the magnitude of local motion vectors depends on the distance between the eyes and the objects in the surroundings, which is not the case in a rotation-induced optic flow. We know the distance-dependence in translation flow fields from everyday experience: When sitting on a train, bushes close by rush past very quickly while trees and hills in the far distance hardly move at all.

Optic flow fields may be projected onto a 2D map of the visual field, which allows us to appreciate its complete structure including both visual hemispheres (Figure 5(c) and 5(d), right panels). This reduction from 3D spherical coordinates to two dimensions in a cylindrical projection, as it is used here, results in overemphasizing the dorsal and the ventral parts of the visual field. While on a sphere, the dorsal and the ventral pole areas consist only of a point, in the cylindrical projection these areas are expanded by factor of $1/\cos\theta$.

In whatever way optic flow is presented, globally, it is always easy to distinguish between translation- and rotation-induced optic flow fields – and thus to identify the self-motion that had caused them. However, both biological and technical systems analyzing directional motion work only locally (e.g., Bulthoff, H. *et al.*, 1989; Borst, A. and Egelhaaf, M., 1993; Barron, J. L. *et al.*, 1994). How directional selective motion detectors in biological systems work and what are the problems associated with local motion processing will be discussed in the next section.

1.06.3.1.2 How does the visual system analyze directional motion?

In the 1950s, Hassenstein and Reichardt carried out a number of behavioral experiments in the beetle *Chlorophanus viridis*. By means of a quantitative input–output analysis they derived a phenomenological model of an elementary movement detector (EMD, Hassenstein, B. and Reichard, W., 1953). This model captures the necessary and sufficient conditions to distinguish between motion in opposite directions. Its functional structure consist of (1) two spatially separated inputs, (2) an asymmetric processing of signals traveling along the two input channels where one signal is delayed in time, and (3) a nonlinear combination of the delayed and undelayed signal realized by a multiplication operation (rev.: Reichardt, W., 1961; 1987; Borst, A. and Egelhaaf, M., 1989). Such EMD responds to motion in its preferred direction with a positive output while motion in the opposite null direction does hardly render any output (Figure 6, upper panels). A fully directional-selective EMD is obtained by summing the outputs of two EMDs with opposite signs, one of which is arranged in a mirror-symmetric way. The summing unit then delivers a positive output when motion in the detector's preferred direction occurs and a negative output for motion in the opposite direction (Figure 6, lower panels). This generic model is also known as a correlation-type motion detector since it performs a spatiotemporal correlation of light intensities sampled at neighboring positions on the retina. Most of the motion detector schemes found across phyla are derivatives of the EMD but have different filters implemented at different processing stages. Borst A.

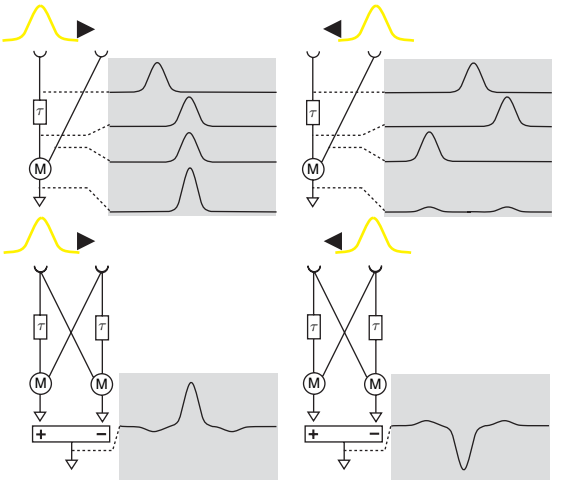

Figure 6 Elementary movement detectors (EMDs). Directional motion in biological systems is analyzed by EMDs, which receive input from and correlate light intensities at neighboring photoreceptors. *Upper left*, half-detector: A light stimulus moving from left-to-right (yellow Gaussian function) is sensed by the left input channel of an EMD first. Propagation of the signal in this channel is delayed by a period of time related to τ, the delay time constant of the EMD. If the time it takes the stimulus to reach the right input channel and the time the signal in the left channel is delayed are the same, both signals simultaneously arrive at the multiplication stage (M) and yield a strong output. *Upper right*: Motion in the opposite direction results in decorrelating the two input signals in time and consequently does not produce a strong output. *Lower left and right*: Subtracting the outputs from two mirror-symmetrical half-detectors results in fully directionally selective properties of the integrating stage. For further explanations see text. Adapted from Borst, A. and Egelhaaf, M. 1989. Principles of visual motion detection. Trends Neurosci. 12, 297–306.

and Egelhaaf M. (1993) provide a comprehensive comparison of different motion detector schemes that were derived either from experimental evidence obtained in different animal systems or from computer vision.

An inherent feature of the EMD is that its output depends not only on the direction and the velocity of visual motion but also on the properties of the visual scene such as contrast and its spatial frequency content (rev.: Buchner, E., 1984; Borst, A. and Egelhaaf, M., 1993). The EMD output depends in a bell-shaped manner on the ratio between the angular velocity at which a pattern of periodic light intensity fluctuations is moving and the pattern's spatial wavelength. Such contrast frequency, or temporal frequency dependence is fundamentally different from the output of another motion detector scheme, the gradient detector, which was originally derived from computer vision (e.g., rev.: Srinivasan, M. V., 1990). Gradient detectors also fulfill the three necessary and sufficient conditions required to analyze motion in a directional-selective way, but their output signals are linear in the velocity domain. Many behavioral and electrophysiological studies have been carried out in the past decades to decide what movement detector schemes different animals use (rev.: Buchner, E., 1984). Although there is good evidence suggesting flies to employ correlation-type motion detectors, bees, for instance, were found to use velocity information to solve many visually controlled tasks (rev.: Srinivasan, M. V. and Zhang, S. W., 2000). It is still an open question whether bees are capable of exploiting velocity information by using gradient detectors or by combining the outputs of correlation detectors tuned to different temporal frequencies – which were indeed found in crabs (Nalbach, H. O., 1989).

The basic structure of the EMD has been revised several times over the years to improve its predictive power (e.g., Clifford, C. W. *et al.*, 1997; Harris, R. A. *et al.*, 1999; Dror, R. O. *et al.*, 2001; Borst, A. *et al.*, 2003) and to investigate its potential of retrieving velocity information (e.g., Reichardt, W. *et al.*, 1988; Zanker, J. M. *et al.*, 1999; Dror, R. O. *et al.*, 2001). Recently in 2D EMD network models, more realistic assumptions about compound eye optics and gain control mechanisms (cf. section 1.06.3.1.3.(viii)) were implemented to overcome the detector's inherent pattern-dependent response properties (Lindemann, J. P. *et al.*, 2003; Shoemaker, P. A. *et al.*, 2005). In particular, when confronted with wide-field stimuli composed of naturalistic spatial frequency distributions (van der Schaaf, A. and van Hateren, J. H., 1996), some of the recent EMD networks performed extremely well to analyze dynamic motion sequences and to predict the activity in directional-selective interneurons (Heitwerth, J. *et al.*, 2005; Lindemann, J. P. *et al.*, 2005; Shoemaker, P. A. *et al.*, 2005).

1.06.3.1.3 Flies as model systems for directional motion processing

The fly is one of the most successful model systems in invertebrate vision and beyond. One of the reasons being that in this animal a variety of experimental approaches in combination with modeling the different processing stages along the visual pathways can be tightly linked to the performance of several visually guided behaviors (rev.: Egelhaaf, M. and Borst, A., 1993; Hausen, K., 1993; Egelhaaf, M. *et al.*, 2002). Not only is the anatomy of the fly

nervous system characterized in minute detail (Strausfeld, N. J., 1976) but also is it possible to investigate the physiological properties of individually identified neurons and neural populations. The extraordinary data body accumulated over the last couple of decades turned out to be an ideal prerequisite to address fundamental questions regarding peripheral and central visual processing and also to study general principles in motion detection, neural coding, mechanisms of adaptation, feature extraction, and, more recently, multimodal integration as well as sensorimotor transformation.

Different fly species are used in research on visual processing: (1) the fruitfly *Drosophila*, for its comparatively easy handling in behavioral experiments and the opportunity to apply neurogenetics to dissect the functional organization of the nervous system; (2) the housefly *Musca*, used in numerous behavioral experiments and several anatomical studies; (3) the blowflies *Calliphora* and *Lucilia*, which are sufficiently big to perform intra- and extracellular electrophysiology as well as optical imaging experiments on identified neurons and neural circuits; and (4) the hoverfly Eristalis, which, again, is accessible to electrophysiological studies.

Working on several different fly species was originally just a matter of practicality: the fruitfly was amenable to neurogenetics but electrophysiological studies were, in the early days, possible only in the bigger blowfly. There were some arguments about whether or not experimental evidence obtained in one species could be transferred straightaway to explain findings in others. Today, however, it becomes more and more obvious that a comparative approach allows us to discover both general principles in visual information processing and species-specific adaptations. For instance, the number of lobula plate tangential cells (LPTCs) constituting the vertical system (VS) (see below) (Hengstenberg, R. *et al.*, 1982), an identified population of visual interneurons, differs between species: While *Drosophila* employs only 6 VS cells, the housefly possesses 8 and *Calliphora* has got even 10 of these interneurons. This difference in terms of neuronal equipment seems to correlate with the complexity of the flight maneuvers the three species are required to control (O'Carroll, D.C. *et al.*, 1996; Buschbeck, E. K. and Strausfeld, N. J., 1997). We will get back to this point in a later section on the relationship between visual processing and motor control. For now, we will stay with LPTCs and discuss their role in processing directional motion information.

1.06.3.1.3.(i) Lobula plate tangential cells and the processing of directional motion Several years after Hassenstein B. and Reichardt W. (1953) derived the functional structure of an EMD the search for its neural correlate started. The input stages were obviously the ommatidia in the compound eye, which contain the photoreceptors sampling light intensities at neighboring locations in the visual field. But where was the multiplication stage located that is so crucial for the EMD to work? Despite a few attempts to identify the multiplication stage (e.g., locusts: Osorio, D., 1986), even today this question remains still unanswered. The summation stage, however, which establishes a fully opponent EMD, was found in the late 1960s and the 1970s. Groups at Caltech, USA, and at the Max-Planck-Institute für biologische Kybernetik in Tübingen, Germany, succeeded in recording the activity of LPTCs in blowflies (Bishop, L. G. *et al.*, 1968; Hausen, K., 1976; Hengstenberg, R., 1977). They found the LPTCs to respond to visual motion stimuli in a motion-sensitive and directional-selective way. In particular, studies at the Max-Planck-Institute in Tübingen over more than 30 years did result in a detailed description of the LPTC response properties. About 60 distinctly different LPTCs were anatomically identified (Hausen, K., 1993).

Most LPTCs possess extended dendritic input fields, which ramify within distinct and conserved parts of the retinotopically organized lobula plate (e.g., rev.: Hausen, K., 1984; 1993). On their dendrites these interneurons integrate the signals of hundreds or, in blowflies, even thousands of directional-selective small-field elements (e.g., Strausfeld, N. J., 1976; Bausenwein, B. and Fischbach, K. F., 1992). The responses of LPTCs when presented with local motion stimuli directly reflect the properties of EMDs (e.g., rev.: Hausen, K., 1984). Several different functional groups of LPTC were anatomically identified and electrophysiologically characterized:

(1) *Heterolateral LPTCs.* They integrate local motion signals obtained from one visual hemisphere and transmit this information via a thin axon to their target neurons in the contralateral part of the brain (e.g., Hausen, K., 1976). These LPTCs are regularly spiking neurons, which allow them to send information at high propagation speeds along the heterolateral pathways (e.g., Hausen, K., 1984; 1993). One of the most famous heterolateral LPTCs is the H1 cell (Hausen, K., 1976), which is used as a general model system to study neural spike coding (e.g., rev.: de Ruyter van Steveninck, R. R. *et al.*, 2001; Warzecha, A. and Egelhaaf, M., 2001).

Another example is the V1 cell (e.g., Hausen, K., 1984), which receives input from several identified VS cells and serves, for instance, as a model system in synaptic transmission and multisensory integration (e.g., Kurtz, R. *et al.*, 2001; Parsons, M. M. *et al.*, 2006).

Spiking LPTCs contribute to virtually all visually guided behaviors based on optic flow processing. Their central role results is due to the fact that only motion information combined from both visual hemisphere allows for an unambiguous distinction between rotation- and translation-induced optic flow (e.g., Krapp, H. G. *et al.*, 2001; rev.: Borst, A. and Haag, J., 2002). Binocular integration certainly takes place at the level of LPTC target neurons such as neck motor neurons (NMNs) and descending neurons (e.g., Gronenberg, W. *et al.*, 1995; Huston, S. J. and Krapp, H. G., 2003). Some tasks, however, require the computation of binocular motion information at the level of the lobula plate already, for instance, in the context of figure-ground discrimination (Egelhaaf, M., 1985a, and see below).

(2) *Output LPTCs.* They come in two distinctly different subpopulations, three horizontal system (HS) cells (Hausen, K., 1982) and ten VS cells (Pierantoni, R., 1976; Hengstenberg, R., 1982; Hengstenberg, R. *et al.*, 1982). The three HS cells, horizontal system north (HSN), horizontal system equatorial (HSE), and horizontal system south (HSS), sample visual information in the dorsal, the equatorial, and the ventral part of the ipsilateral visual field, respectively (Hausen, K., 1982). HSN and HSE receive additional rotation-specific input from the contralateral visual field mediated by heterolateral spiking LPTCs (Hausen, K., 1993; Krapp, H. G. *et al.*, 2001). The morphology of VS cells, numbered from VS1–VS10, is distinctly different from the HS cell morphology in that their main dendrites are not horizontally but vertically oriented. The VS1 main dendrite arborizes in the distal lobula plate and samples motion information within the frontal visual field, while the VS10 main dendrite ramifies in the proximal lobula plate receiving its retinotopic input from the caudal visual field (Krapp, H. G. *et al.*, 1998). Altogether the VS cell receptive fields cover the entire visual hemisphere.

The dendrites of VS and HS cells mostly ramify in four distinct directional input layers of the lobula plate. These layers convey information about vertical and horizontal motion presented in the equatorial visual field (Buchner, E. *et al.*, 1979). However, there are some exceptions: VS1, for instance, has got a second dendritic tree that arborizes in the most anterior directional input layer mediating horizontal back-to-front motion sensitivity (Hengstenberg, R. *et al.*, 1982; Hausen, K., unpublished). Furthermore, the proximal VS cells, VS7–VS10, possess dendritic side branches receiving input from the second most anterior input layer mediating horizontal front-to-back motion sensitivity. The HS cell dendrites also ramify within the second most anterior layer (Hausen, K., 1982; Hausen, K., unpublished; Hengstenberg, R. *et al.*, 1982).

When first discovered, the signals that output LPTCs generate were distinctly different from those of spiking heterolateral LPTCs. Motion in the neurons' preferred direction resulted in a depolarizing membrane potential shift while motion in the opposite null directions did hyperpolarize the cells. Pharmacological studies did show that VS and HS cells are equipped with ACh- and GABA receptors, which suggests these cells to receive input from the two mirror-symmetrical subunits of an EMD, one excitatory and the other one inhibitory (Brotz, T. M. and Borst, A., 1996). It is still debated, though, whether local input elements presynaptic to the LPTCs are already fully directional-selective (Douglass, J. K. and Strausfeld, N. J., 1995; Douglass, J. K. and Strausfeld, N. J., 1996).

On top of the graded response to preferred direction motion, superimposed spikelets of irregular amplitude were found (Hengstenberg, R., 1977). Later, the application of channel blockers did show that the irregular spikelets are in fact regular sodium spikes (Haag, J. and Borst, A., 1996). The small and irregular amplitudes of spikelets were concluded to be the result of a comparatively shallow resting potential in VS and HS cells. At about −50 mV resting potential, only a smaller fraction of sodium channels will contribute to a spike since not all channels would have completed the transition from the closed nonactivatable to the closed activatable state. The comparatively low input resistance mainly responsible for the shallow resting potential shortens the cells' time constant and thus increases its bandwidth (Haag, J. and Borst, A., 1996). The faster responses, however, also mean that the LPTCs are more expensive in terms of energy consumption (Laughlin, S. B., 2001). Meanwhile, most aspects of passive and active response properties in VS and HS cells could be explained by combining thorough electrophysiological experiments and compartmental modeling (Borst, A. and Haag, J., 1996; Haag, J. *et al.*, 1999; rev.: Borst, A. and Haag, J., 2002).

The axon terminals of VS and HS neurons ramify ipsilaterally within the ventrolateral protocerebrum where they make contact with their target neurons via mixed chemical–electrical synapses (Strausfeld, N. J., 1976; Strausfeld, N. J. and Bassemir, U. K., 1983;

Gauck, V. *et al.*, 1997). Their postsynaptic targets are mostly descending neurons (Gronenberg, W. and Strausfeld, N. J., 1990; Strausfeld, N. J. and Gronenberg, W., 1990) projecting to various motor neuropils in the thoracic ganglia and some motor neurons controlling the neck motor system (Gilbert, C. *et al.*, 1995; Gronenberg, W. *et al.*, 1995). The LPTC target area also contains output arborizations of afferent fibers from other sensory systems, such as the ocelli and the antennae, as well as from ascending neurons, which convey information from the thoracic neuropils (Strausfeld, N. J. and Seyan, H. S., 1985).

The functional significance of HS and VS LPTCs for visual stabilization reflexes was conclusively shown by a number of lesion experiments using different approaches. In *Drosophila*, the neurogenetic mutant omb^{H31} produces flies that do not develop HS and VS cells (Heisenberg, M. *et al.*, 1978). These mutants loose their inner-loop control, i.e., they fail in course and gaze stabilization tasks (Blondeau, J. and Heisenberg, M., 1982; Hengstenberg, R., 1995). But they remain capable of distinguishing object from background motion – indicating a separate neural pathway that may be used for outer-loop control, for instance, during chasing of small targets. Laser ablation and microsurgical lesion experiments in *Calliphora* larvae and adults, respectively, both causing dysfunction of the HS and VS led to similar results (Geiger, G. and Nässel, D. R., 1981; Hausen, K., and Wehrhahn, C., 1983).

(3) *Centrifugal LPTCs, CH cells.* These cells receive input at least at two different locations. First, with respect to the location of their cell body, they collect information from the ipsilateral protocerebrum where the terminals of output LPTCs arborize (rev.: Hausen, K., 1993). Second, they receive retinotopic input the HSE cell mediates to their contralateral arborizations in the lobula plate. Ultrastructural studies revealed colocalizations of input and output specializations on the extended contralateral arborizations of the CH cells (Gauck, V. *et al.*, 1997). Centrifugal cells generate graded membrane potential shifts without any superimposed sodium spikelets (rev.: Hausen, K., 1984). Their membrane potential fluctuations during visual stimulation reveal input from several spiking neurons causing distinctly different excitatory and inhibitory postsynaptic potentials (rev.: Hausen, K., 1984; Haag, J. *et al.*, 1999). Centrifugal cells are GABAergic and were shown to be key elements in an intrinsic lobula plate circuit involved in figure detection (FD; Egelhaaf, M., 1985c, and see below).

(4) *FD cells* (Egelhaaf, M., 1985b; rev.: Hausen, K. and Egelhaaf, M., 1989; Gauck, V. and Borst, A., 1999). The size dependence of FD cell responses is fundamentally different from that of all other LPTCs whose responses increase to a certain degree as the stimulus pattern size is increased. FD cells, instead, respond strongly to motion of small objects moving out of phase with wide-field background motion. As the size of the object increases the FD cell response decreases (Egelhaaf, M., 1985b). The way in which such small-field tuning is established could be demonstrated experimentally in case of the identified FD 1 cell. FD 1 receives input from the ventral centrifugal cell, VCH, also called a wide-field inhibitor. When the impact of the wide-field inhibitor was abolished either by applying GABA blockers or by laser-ablating the cell, FD 1 transformed into an ordinary, wide-field-tuned LPTC (Warzecha, A. K. *et al.*, 1993). Combined behavioral and electrophysiological experiments suggest FD cells to distinguish objects of potential interest from the background by using relative motion cues (Reichardt, W. and Poggio, T., 1976; Egelhaaf, M., 1985a; 1985b; 1985c).

1.06.3.1.3.(ii) HS and VS cells analyze self-motion-induced optic flow For many years HS and VS cells as well as heterolateral LPTCs were distinguished based on their predominant directional motion preferences, that is, horizontal front-to-back motion and vertical downward motion. In case of HS and VS cells, the overall orientation of their main dendritic branches within the different direction-specific input layers of the lobula plate also justified the distinction between horizontal and vertical cells. From the functional point of view, knowing both the horizontal and the vertical motion component at any location in the visual field would require only little additional computation to retrieve the exact direction of local motion.

Only in the mid-1990s, an alternative idea was put forward that would considerably simplify the extraction of self-motion parameter from optic flow fields. The hypothesis was that individual LPTCs were tuned to extract information about self-motion in a more specific way (Krapp, H. G. and Hengstengberg, R., 1996). To extract, for instance, the roll component of self-motion the local motion preferences within the receptive field of a VS cell should match the orientation of local velocity vectors in an optic flow field that is generated when the fly turns around is longitudinal body axis. Such a matched filter for particular self-motion components would get around the problem that local motion information is insufficient to infer what self-motion had caused it (Figure 7). This hypothesis assumed, however, that the distribution of local

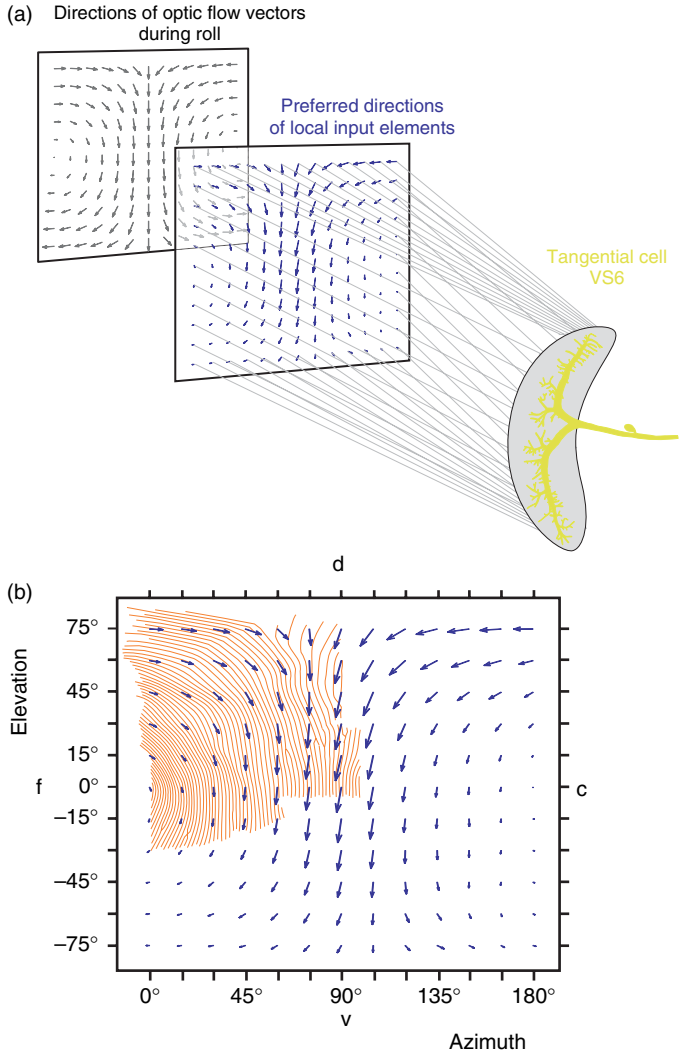

Figure 7 Lobula plate tangential cells (LPTCs) process optic flow. (a) To indicate roll rotation the VS6 cell selectively integrates the output of those local input elements whose preferred directions match the local orientation of velocity vectors in an optic flow field generated during roll. (b) The visual VS6 receptive field (same as in (a)) is shown in a cylindrical projection of the right visual hemisphere. The distribution of local preferred directions is indeed very similar to the vector distribution within a roll optic flow field (cf. Figure 5d, right half). Orange curved lines in the upper left quadrant give the course of ommatidial rows, the orientation of which is vertical in the eye equator (elevation = 0°). Note that these vertical rows are considerably distorted in the frontodorsal part of the eye and become almost horizontally oriented at most dorsal locations. Also note the striking similarity between the VS6 cell's local preferred directions and the local vertical row orientations in that area. This correlation reflects the anatomical arrangement of retinotopic inputs in the periphery at the most central level of directional motion processing, the lobula plate. For further explanation see text. Adapted from Egelhaaf, M., Kern, R., Krapp, H. G., Kretzberg, J., Kurtz, R. and Warzecha, A. K. 2002. Neural encoding of behaviourally relevant visual-motion information in the fly. Trends Neurosci. 25, 96–102.

motion preferences would gradually change in a position-dependent way altogether approximating the directional distribution of local velocity vectors within specific optic flow fields.

A detailed receptive field characterization using a local stimulation procedure (Krapp, H. G. and Hengstenberg, R., 1997) revealed that none of the LPTC receptive fields shows an isotropic distribution of local preferred directions. The results of several studies applying intracellular and extracellular recording techniques did indeed support the hypothesis that individual LPTCs are tuned to sense distinct self-motion components (Krapp, H. G. and Hengstenberg, R., 1996; Krapp, H. G. *et al.*, 1998;

rev.: Krapp, H. G. 2000; Krapp, H. G. *et al.*, 2001). Not only was the distribution of local preferred directions matches to estimate certain self-motion components. The local motion sensitivities within the receptive fields of some LPTCs were also adapted to optimize the distinction between rotation- and translation-induced optic flow (Figure 8). Analytical modeling did suggest that the decreased sensitivity to motion in the ventral receptive field of VS cells extracting the roll component is an optimal strategy to produce a response more or less independent of any superimposed translation flow (Franz, M. O. and Krapp, H. G., 2000). This makes perfect sense for a matched filter for roll rotation. Optic flow in the ventral visual field, where the distance to the visual structures is small, would be dominated by translation-induced flow that distorts the roll-specific flow vectors. In the dorsal visual field, however, the distances to visual structures are far greater, which means that the translation-induced optic flow is very small, if not zero (cf. eqn [1]. LPTCs estimating translation components show higher motion sensitivities in the ventral than in the dorsal visual field (Franz, M. and Krapp, H. G., 2000).

The anisotropic distribution of motion sensitivities within the receptive field of LPTCs suggests that the fly visual system makes assumptions about the average distance distribution usually encountered in the environment. Implementing prior knowledge is one measure to increase the reliability at which specific self-motion parameters can be extracted from optic flow (Dahmen, H. *et al.*, 2001).

1.06.3.1.3.(iii) Monocular and binocular integration of motion information From eqns [2] and [3] it follows that a reliable estimation of the self-motion parameters **R** and **t** will also benefit from an extended

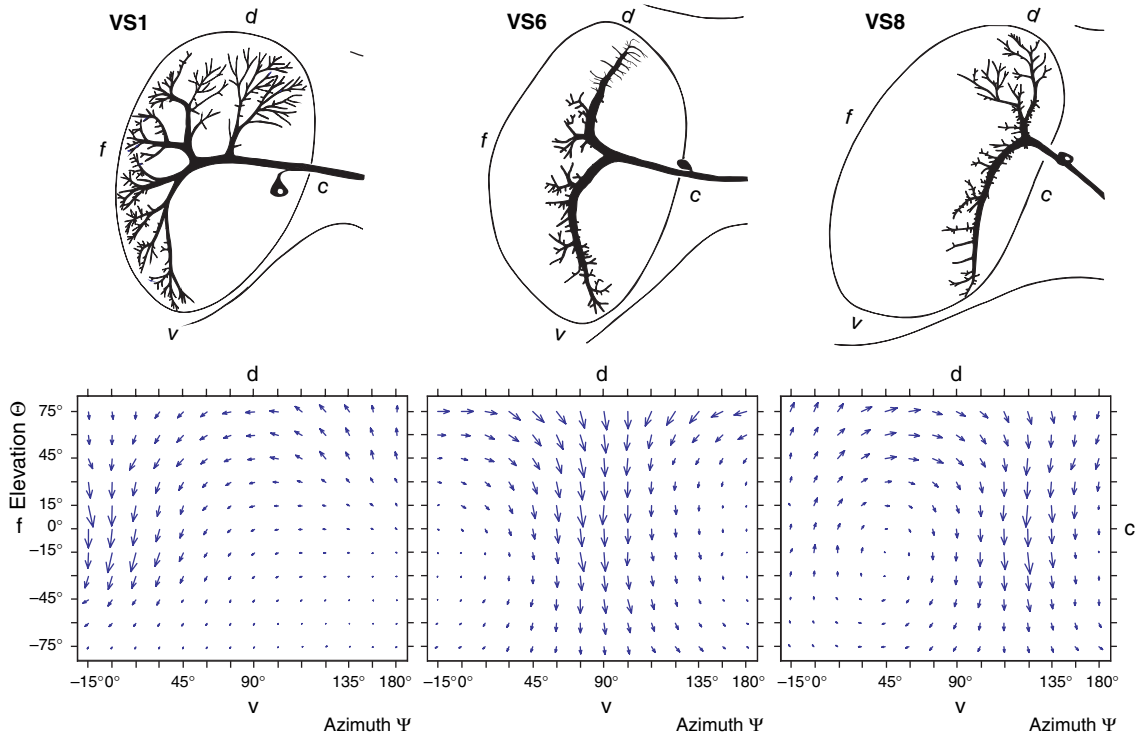

Figure 8 Vertical cells indicate self-rotations around horizontal body axes. Upper row of panels: The reconstructions from intracellular staining of individually identified tangential cells VS1, VS6, and VS8 drawn in the contours of the lobula plate. Lower row of panels: The visual receptive fields averaged across results obtained from at least five different flies per cell type. All receptive fields show a smooth transition of local motion preferences reminiscent of the directional gradient of velocity vectors in parts of or in an entire monocular rotation flow fields. Note that the location of the main vertical dendrite within the lobula plate corresponds to the positions where the respective cells are most sensitive to vertical downward motion within the visual field. In case of the VS1 cell the extent of its dendritic arborizations within the lobula plate is in agreement with the size and the location of the cells' receptive field, assuming a retinotopic input organization. This is not the case for VS6 and VS8. For further explanation see text. Adapted from Krapp, H. G. and Hengstenberg, R. 1996. Estimation of self-motion by optic flow processing in single visual interneurons. Nature 384, 463–466. Krapp, H. G., Hengstenberg, B. and Hengstenberg, R. 1988. Dendritic structure and receptive-field organization of optic flow processing interneurons in the fly. J. Neurophysiol. 79, 1902–1917.

area across which local flow measurements are taken. Ideally, to get rid of the apparent rotation and translation terms in these equations, measurements should be distributed in sufficient numbers and at locations so that $<\mathbf{d}_i>$ vanishes. In this case the apparent terms become zero, and **R** and **t** can be reliably estimated.

This consideration immediately explains why heterolateral elements are needed. Heterolateral elements establish a binocular receptive field. Interestingly, only a few LPTCs were found to have truly binocular receptive fields in the sense that they respond equally well to motion in either visual hemisphere. A prime example is the centrifugal cell VCH, the wide-field inhibitor of the FDI cell (Warzecha, A. K. *et al.*, 1993, and see above). In case of the figure detection circuit, binocular integration needs to take place at the level of the lobula plate to facilitate the specific action of the wide-field inhibitor, that is, the subtraction of wide-field background motion. Most of the output LPTCs, however, receive only weak, often quite variable contralateral input. The reason for this is not exactly clear but might be related to the internal physiological state of the individual fly. More substantial binocular integration takes place at the level of the neurons postsynaptic to the output LPTCs. This was shown for fly neck motor neurons and some descending neurons (e.g., Gronenberg, W. *et al.*, 1995; Huston, S. J. and Krapp, H. G., 2003). The most reasonable explanation is that binocular integration only at the level of the LPTC target neurons gives the system more flexibility. In combining the outputs of different LPTCs the target neurons' receptive field properties could be tuned more specifically to encode certain self-motions and to comply with the needs of the various motor systems they supply (Section 1.06.7.2). This strategy would significantly simplify the sensory motor transformation where information obtained in sensory coordinates has to be converted into signals controlling movements in motor coordinates (see Section 1.06.6).

Most of the heterolateral LPTCs themselves are sensitive to binocular motion. But again, as in output LPTCs the overall sensitivity is usually higher when motion stimuli are presented within the ipsilateral hemisphere. How the contralateral motion sensitivities are established is not exactly known as yet. The receptive field organization of these cells suggests, however, that direct or indirect mutual coupling takes place between heterolateral LPTCs from either side of the visual system (rev.: Borst, A. and Haag, J., 2002). Recent studies further developed earlier ideas of how network interactions among LPTCs may increase the neurons' flow field specificity (rev.: Hausen, K. 1993; Borst, A. and Haag, J., 2002; and see below).

1.06.3.1.3.(iv) Synaptic transmission: the VS–V1 synapse Combining motion information from either side of the visual field to increase optic flow specificity in LPTCs poses a couple of challenges. For instance, LPTCs receiving retinotopic input may be faster in integrating the signals than a heterolateral element would be able to integrate and transmit information from the contralateral eye. As a result there might be a time lag between ipsi- and contralateral optic flow information. How such synchronization issues are solved is currently unclear.

Another challenge concerns the synaptic signal transmission in heterolateral pathways. Assuming that the activity level in heterolateral and output LPTCs is related to rotation velocity in a similar way, ideally, their signals should be combined linearly. Graded chemical synapses, however, are known to involve several nonlinear processes, for example, the cooperative action of calcium on vesicle release (Dodge, F. A., Jr. and Rahamimoff, R., 1967; Smith, S. J. *et al.*, 1985).

Recent electrophysiological and optical imaging studies (Kurtz, R. *et al.*, 2001; Warzecha, A. K. *et al.*, 2003) did aim at characterizing the transfer properties of identified synapses between VS cells and the heterolateral LPTC, V1 (e.g., Hausen, K., 1984). The V1 cell receives input from four VS cells, VS1–VS4, as suggested by its receptive field organization (Krapp, H. G. and Hengstenberg, R., 1997; Krapp, H. G. *et al.*, 1998) and shown by means of simultaneous double recordings (Kurtz, R. *et al.*, 2001; Warzecha, A. K. *et al.*, 2003). The relationship between the spike rate in the postsynaptic V1 and both the membrane potential and the calcium concentration changes in individual presynaptic VS cells was found to be nearly linear. This finding suggests that the VS–V1 synaptic transmission operates in a linear range benefiting a meaningful integration of binocular motion information (ibid.). Laser ablation of individual VS cells led to the conclusion that VS2–VS4 transmit through chemical synapses while VS1 is electrically coupled to the V1 cell (Kalb, J. *et al.*, 2006). Kalb J. *et al.* (2006) conclude that the redundancy in the V1 input, that is, four VS cells contribute to the input, may increase the accuracy and the robustness of the heterolateral pathway in encoding self-motion information. Another possible reason, however, might be related to the time delay

issues in heterolateral pathways mentioned above. VS1–VS4 cells are tuned to slightly different preferred rotation axes (Krapp, H. G. *et al.*, 1998) and were found to be electrically coupled (e.g., Haag, J. and Borst, A., 2004). Both properties may improve the encoding of a dynamic self-motion sequence during a specific flight maneuvers rather than establishing a narrow static tuning to one particular rotation axis.

1.06.3.1.3.(v) How to explain the receptive field properties of LPTCs? When the detailed receptive field organization of LPTCs was discovered and their specific function in the context of optic flow processing became obvious (Krapp, H. G., 2000), one of the most intriguing questions to ask was: does such sophisticated distribution of local motion preferences depend on early visual experience? Classical deprivation experiments on kittens first showed that early visual experience is essential to properly develop the functional organization of the visual cortex (Hubel, D. H. and Wiesel, T. N., 1965). Despite the common preconception that the nervous system of most insects must be hardwired, several experiments did show a significant degree of plasticity in the developing fly visual system (behavior: Mimura, K., 1986; neuroanatomy: Barth, M. *et al.*, 1997; Rybak, J. and Meinertzhagen, I. A., 1997). Comparing the receptive field organization of the heterolateral LPTCs (V1 and H1) obtained in normally raised flies and in flies deprived of any visual input shows that the receptive field organization of the LPTCs is innate. This suggests that the adaptation to specific optic flow processing has happened on the phylogenetic timescale (Karmeier, K. *et al.*, 2001).

If not at all depending on visual experiences what determines the gradual changes of motion preferences within different parts of the receptive fields of the LPTCs? Hausen K. (1984) already pointed out that motion preferences of some LPTCs may be related to the anatomical organization of the compound eye. This comparison was probably inspired by earlier behavioral studies showing that directional motion information used for locomotor control in light-adapted flies correlates to 70% with the interactions of neighboring ommatidia along the hexagonal eye lattice (Buchner, E., 1976). Supporting evidence for a link between the orientation of the eye lattice and the processing of directional motion information came from electrophysiological studies also (Schuling, F. H. *et al.*, 1989). In a more recent study, the local orientation of ommatidial rows in the blowfly compound eye was determined for the frontodorsal quadrant of the eye (Petrowitz, R. *et al.*, 2000). A qualitative comparison revealed a remarkable correspondence between ommatidial row orientation and local motion preferences within monocular receptive fields of both HS cells and a subgroup of VS cells (Figure 7(b)); Egelhaaf, M. and Krapp, H. G., 1999; rev.: Egelhaaf, M. *et al.*, 2002). These findings suggests that the receptive field organization of some LPTCs may be explained directly from the geometrical arrangement of ommatidia in the hexagonal eye lattice. It is tempting to assume that the eye geometry, the most peripheral stage of the fly visual pathway, already serves as a filter that facilitates the processing of directional motion information in a task-specific way. Obviously, such adaptation to analyze optic flow would make sense only if it did not compromise the processing of visual information required for the control of other behaviors.

1.06.3.1.3.(vi) Lobula plate tangential cell network interactions Even though some of the local LPTC response properties could be directly understood from the eye geometry, there were still two open questions: Given that the LPTCs integrate local motion information in a retinotopic way, it should be possible to infer the size of the ipsilateral receptive field from the cells' dendritic arborization pattern within the lobula plate. While this is perfectly possible for the HS cells, several heterolateral LPTCs, and the centrifugal cells (Hausen, K., 1993; Krapp, H. G., 1995; Krapp, H. G. unpublished data; Krapp, H. G. *et al.*, 2001), the receptive field size of some VS cells is considerably larger than their dendritic arborization pattern suggests (Figure 8, cf. VS6 and VS8).

More recent electrophysiological studies solved this issue. By simultaneous intracellular recordings from pairs of VS cells, Haag J. and Borst A. (2004) were able to show that neighboring VS cells are coupled via electrical synapses. When injecting current into the most distal VS1 cell and measuring the membrane potential in increasingly more proximal VS cells, a monotonous decay of the coupling strength up to VS7/8 was found (Haag, J. and Borst, A., 2004). The coupling between VS1 and the most proximal VS9 and VS10 shows even a sign inversion. To explain the sign inversion, an ipsilateral spiking interneuron was suggested (ibid.). Further laser ablation experiments confirmed the ipsilateral coupling between VS cells (Farrow, K. *et al.*, 2005). Such ipsilateral network interactions (Figure 9) may indeed explain why proximal VS cells, which lack any dendritic arborization in the distal lobula plate, do nonetheless respond perfectly well to motion stimuli presented in the frontal visual

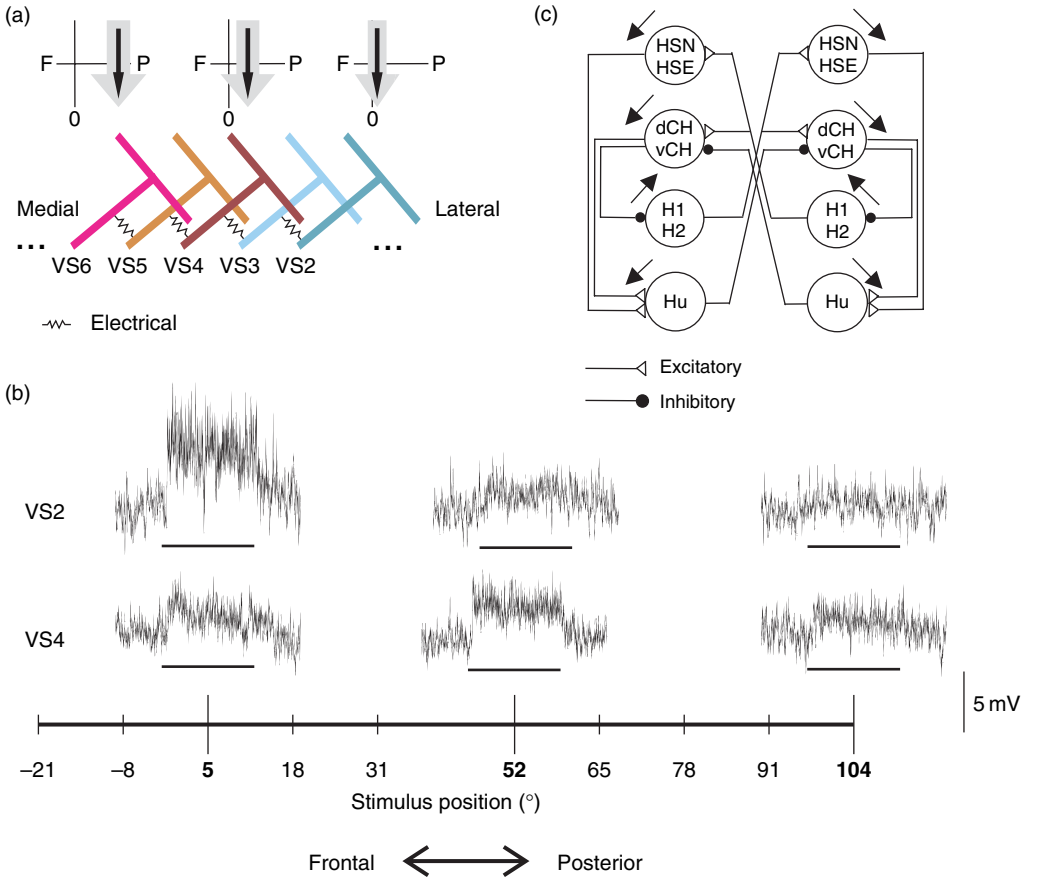

Figure 9 Network interactions between lobula plate tangential cells (LPTCs). (a) Simultaneous intracellular recordings from pairs of vertical system (VS) cells demonstrated ipsilateral network connections among VS neurons mainly mediated by electrical coupling. Broad gray arrows roughly indicate the extent of downward sensitivity within the VS cells receptive field at a center position given by the black arrow. (b) Simultaneous double recording of VS2 and VS4 shows that the activity induced by vertical downward motion depends on the position of the stimulus along the azimuth. If the stimulus is positioned in the frontal visual field, VS2 is stronger activated while VS4 responds stronger to downward motion at around 50° azimuth. Horizontal bars below intracellular traces, 1 s. For further explanations see text. Adapted from Farrow, K., Borst, A., Haag, J. 2005. Sharing receptive fields with your neighbors, tuning the vertical system cells to wide field motion. J. Neurosci. 25, 3985–3993. (c) Summary diagram showing heterolateral and ipsilateral network interactions among horizontal LPTCs. The interactions may be excitatory (open triangles) or inhibitory (filled circles) and all together are believed to increase the selectivity for sensing yaw rotation as opposed to thrust translation. H1, H2, and HU are spiking heterolateral cells, while HSE, HSN, dCH, and vCH respond to visual motion mainly by graded membrane potential shifts. For further explanation see text. Adapted from Haag and Borst 2001.

field. Together ipsilateral and heterolateral network interactions were thought to further increase the optic flow specificity in LPTCs (Haag, J. and Borst, A., 2001; rev.: Haag, J. and Borst, A., 2002; 2003; Farrow, K. *et al.*, 2005; 2006).

1.06.3.1.3.(vii) Robustness of encoding self-motion parameters A couple of years ago, much attention was paid to the nature of the neural code. In this context the fly spiking H1 cell did once again serve as a model system to study a fundamental issue in neuroscience. Different data analysis techniques, including information theory (Shannon, C. E. and Weaver, W., 1949), tried to solve the question as to whether rate coding or the exact timing of individual spikes is more important in information processing (de Ruyter van Steveninck, R. R. *et al.*, 1997; Warzecha, A. K. and Egelhaaf, M., 1999). Theoretical considerations in combination with outdoor electrophysiology led to the conclusion that the reliability of

reconstructing motion information in the fly visual system was limited only by photon noise (Lewen, G. D. *et al.*, 2001). Other groups, however, suggested noise in the neural circuits to determine the systems' accuracy (Warzecha, A. and Egelhaaf, M., 2001). While several studies aimed at deciding the coding question in one or the other way (rev.: de Ruyter van Steveninck, R. R. *et al.*, 2001; Warzecha, A. and Egelhaaf, M., 2001), it is still not clear what coding strategy the fly uses. The answer may come from studies on target neurons, which decode self-motion information that LPTCs provide. Eventually, more quantitative behavioral experiments are needed to test whether the exact timing of individual spikes in the fly motion vision pathway, affects the animals behavioral performance, which ultimately define the benchmark for neural coding.

The LPTC studies on the neural code were limited in that they focused only on one stimulus parameter, the yaw angular velocity. Recently, a question was raised more directly related to the function of LPTCs, which is the estimation of self-motion parameters. While angular velocity may be detected within a small patch of the receptive field, encoding self-motion parameters ideally involves the entire binocular visual space and requires selective integration of local motion information (see Section 1.06.3.1.3.(iii)). If individual LPTCs did encode particular self-motion components, as their local response properties suggest (Krapp, H. G. and Hengstenberg, R., 1996; rev.: Krapp, H. G., 2000), then each cell should prefer wide-field motion mimicking a specific self-motion of the animal. VS cells did indeed show a preference for wide-field motion patterns rotated around those axes predicted from the cells' local response properties (Karmeier, K. *et al.*, 2005). The tuning of the spiking V1 cell to its preferred rotation axis was robust even if the rotation flow field was superimposed with translation-induced optic flow (Karmeier, K. *et al.*, 2003).

But how quickly and accurately the entire population be able to encode any arbitrary rotation axis in the horizontal plane? Karmeier K. *et al.* (2005) addressed this question using Bayesian inference to estimate the rotation axis by considering the responses of all 10 VS cells and produced some interesting results: Considering the entire population shortens down the time interval over which the signals of the cells need to be integrated even if the intrinsic noise of the cells is correlated. Within less than 20 ms, the estimation error in determining the rotation axis is reduced to $<10^{\circ}$ (Karmeier, K. *et al.*, 2005). This time interval comes close to the consecutive time intervals of rotation and translation phases observed during semifree flight experiments in blowflies (Schilstra, C. and van Hateren, J. H., 1999). Another interesting aspect of the population code study concerns a question that has long been puzzling researchers in the field: Why using 10 VS cells to encode horizontal rotations when 2 VS cells would be sufficient from the theoretical point of view? The answer is partly that, given noise correlations and time constraints, a higher number means faster and more accurate estimations. Too many neurons, however, would result in higher energy consumption – a constraint inherent to sensory processing (Laughlin, S. B., 2001). Later we will discuss another explanation regarding the number of VS cells in Calliphora, which may be related to the efficiency of sensorimotor transformations (see Section 1.06.6.2).

1.06.3.1.3.(viii) Gain control and motion adaptation

All sensory systems share another common problem: Dynamic range matching. While the amplitude range of sensory stimuli often spans several orders of magnitude the dynamic response range within which a neuron can modulate its activity is drastically limited. A simple solution to this problem, for instance, scaling the input range, would work only in noise-free systems coding information in an ideal analog way. Neural systems, however, are everything but noise-free and at processing stages such as sensory transduction (see Chapter Phototransduction in Microvillar Photoreceptors of Drosophila and Other Invertebrates), synaptic transmission (see Section 1.06.3.1.3.(iv)), and signal propagation, discretization takes place. Even for image processing in semiconductor circuits, using the purest materials available, dynamic range compression is a serious issue. How do biological systems, built from proteins, fat, ions, and water, which – on top it – operate under permanent energy constraints (Laughlin, S. B., 2001) deal with this problem?

A general principle in sensory processing is to emphasize on significant changes in stimulus space by adapting the system's operating range. An efficient way of adaptation is to increase the sensitivity to a stimulus range where changes are most likely to occur. One possibility, for instance, would be high-pass filtering the signals to remove any DC signal components and thus to increase the gain on signal changes. In the peripheral visual system, such strategies were demonstrated at several stages (rev.: Laughlin, S. B. and Hardie, R. C., 1978; Laughlin, S.

B., 1989; Weckstrom, M. *et al.*, 1991; Land, M. F., 1997).

How about adaptation in LPTCs when processing wide-field motion stimuli? Flies reach translation velocities of up to 3 m s^{-1} (Taylor, G., personal communication) and may rotate at angular velocities exceeding 3000° per second. Without any measures of adaptation or gain control mechanisms, the output range of the LPTCs would be constantly at risk to saturate.

1.06.3.1.3.(viii).(a) Dendritic gain control In behavioral experiments on the housefly, Reichardt, W. *et al.* (1983) made an interesting observation when examining the intended yaw torque in response to stimulus patterns of different size rotated around the animal. First the fly increased its torque response with increasing pattern size. But beyond a certain size the response stayed at a plateau level that was dependent on pattern velocity: higher pattern velocities produced higher plateau levels (Figure 10(a)). The velocity dependence of the plateau levels obviously shows that the plateaus were not caused by an output saturation but, instead, a mechanism was in place that controlled the gain of the behavioral response (Reichardt. W. *et al.*, 1983). Based on their results, Reichardt W. *et al.* (1983) proposed two cells to receive the signals from all the EMDs activated during stimulation: a pool cell and an output cell, the latter of which controls the yaw torque. The integrated signal of the pool cell is then used to presynaptically inhibit all local elements connected to the output cell. Such shunting inhibition model requires the pool cell's output to be logarithmically compressed and an expansive gain at the site of the presynaptic inhibition. Altogether the model produces an invariant response with respect to the pattern size that scales with pattern velocity (ibid).

Later electrophysiological experiments on LPTCs provided an alternative explanation for the behavioral findings based on a biophysical model (Borst, A. *et al.*, 1995). The responses of EMD half-detectors were found to be less directional-selective than previously assumed. When challenged with preferred direction motion not only ACh-gated sodium channels changed their conductance resulting in a depolarization of an LPTC but also a fraction of GABA-gated chloride channels opened reducing the overall depolarization. The ratio of sodium and chloride channels activated did depend on pattern velocity (Figure 10(b)). The higher the pattern velocity, generally resulting in higher LPTC response amplitudes, the more chloride channels were activated effectively limiting the cell's

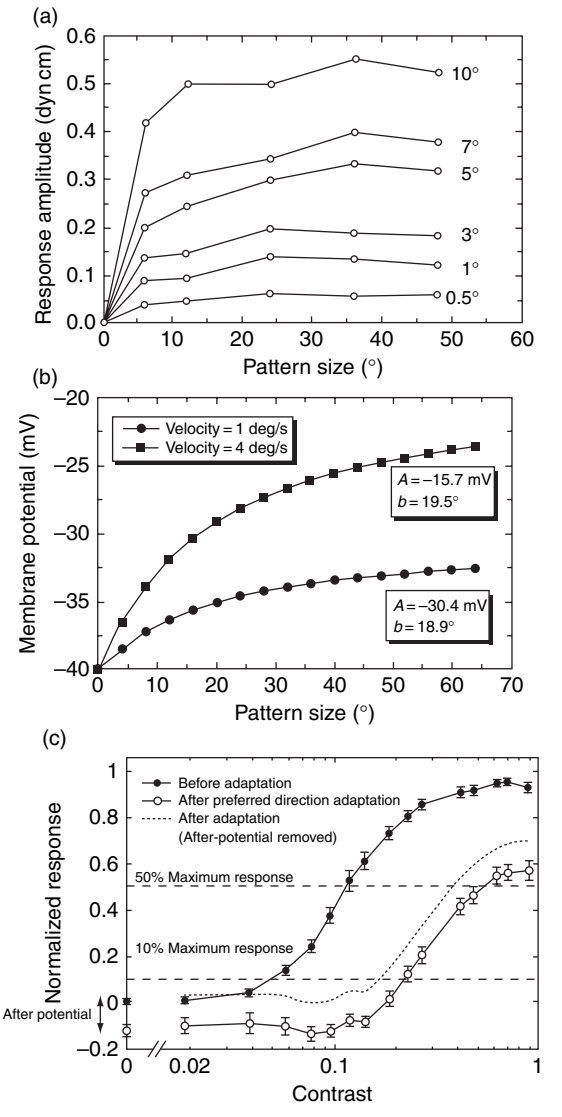

Figure 10 Gain control. (a) Output gain control in behavioral experiments on *Musca*. The response amplitude is plotted against the size of a moving background pattern oscillating at different amplitudes from 0.5° up to 10°. Beyond a certain pattern size the response stays a plateau level that depends on the respective pattern velocity. (b) Dendritic gain control simulations show similar results. The simulated membrane potential changes depend on pattern size in a qualitatively similar way. The velocity-dependent plateau responses were obtained by assuming differences in the ratio of excitatory and inhibitory conductances activated during directional motion stimuli presented at different speeds. For further explanation see text. Adapted from Borst, A. *et al.*, 1995, data in A from Reichardt, W., *et al.*, 1983. (c) Contrast gain function in the hoverfly before (filled circles) and after motion adaptation (open circles). Due to motion adaptation the contrast sensitivity function is shifted to the right, slightly compressed, and shifted downward by a hyperpolarizing afterpotential. For further explanation see text. Adapted from Harris, R. A., O'Carroll, D. C., Laughlin, S. B. 2000. Contrast gain reduction in fly motion adaptation. Neuron 28, 595–606.

output signal. Such dendritic gain control mechanism leads to a sublinear integration of local inputs and does not require the normalization of a pool cell (Borst, A. *et al.*, 1995). It was also found that dendritic integration in LPTCs depends on the spatial relationship of simultaneous inputs. Sublinear integration is more pronounced when local stimuli are presented in close proximity to one another while more distant stimuli produce almost a linear sum of the individual local responses (Haag, J. *et al.*, 1992). This phenomenon is nicely explained by the passive dendritic properties of the LPTCs in combination with the cell's extended dendritic morphology. Stimulus-induced opening of sodium channels results in the cell's depolarization but at the same time reduces its local input resistance. This attenuates the effect of further channel openings due to additional stimulation at neighboring locations. Since LPTCs are not electrotonically compact, additional stimulation that results in conductivity changes taking place further away or on different dendritic branches will not have such an attenuating effect. Altogether, the dendritic integration properties of LPTCs have two important functional consequences: (1) they prevent output saturation and (2) render the cells' responses to be mostly independent of the density of visual contrasts in a given environment.

1.06.3.1.3.(viii).(b) Contrast gain reduction Besides dendritic gain control, other mechanisms have been proposed to prevent LPTC output saturation or to increase the motion pathway's sensitivity to detect changes in image velocity. One idea was that the delay filter in the EMD may adapt to keep the doctor's sensitivity to velocity changes independent of the average image velocity it encounters (Maddess, T. and Laughlin, S. B., 1985; de Ruyter van Steveninck, R. R. *et al.*, 1986; Borst, A. and Egelhaaf, M., 1987). Later studies, however, did not confirm the presence of an adaptable time constant in the EMD (Harris, R. A. *et al.*, 1999). Another suggestion was that the H1 cell performs a dynamic adaptive rescaling of its input–output characteristics, which adjust the cell's sensitivity to the variance of the image velocities it is challenged with (Fairhall, A. L. *et al.*, 2001). The physiological mechanisms underlying such adaptation remain unknown, though.

A recent study by Harris R. A. *et al.* (2000) describes another way of coping with both dynamic range matching and preventing LPTC output saturation: contrast gain reduction. The contrast sensitivity function obtained from intracellularly recorded HSE cells in the hoverfly *Eristalis* was found to be transformed in three different ways after presenting strong adapting motion stimuli: (1) the contrast sensitivity function was shifted to the right – so that, after motion adaptation, higher contrasts were required to reach a certain response level. (2) The contrast sensitivity function was also shifted vertically because of the subtractive effect of an after hyperpolarization in the cell. And (3) the cell's output range was slightly compressed. The strongest of these effects by far resulted from a contrast gain reduction, which was found to be independent of the cell's activity level and, thus, nondirectional (Figure 10(c), Harris, R. A. *et al.*, 2000). There is no experimental evidence so far suggesting at which level along the motion detection pathway the contrast gain reduction operates. A sensible stage for the mechanism to kick in would be located before the two input signals are passed through the multiplication operation in the EMD (ibid), which causes an expensive relationship between image contrast and detector output (rev.: Buchner, E., 1984; Reichardt, W., 1987). The comparatively small subtractive effect of after-hyperpolarization is the only component whose magnitude depends on the direction of the adapting stimulus. The after-hyperpolarization might be caused by calcium accumulation in the cell, which results in an increase of calcium-dependent potassium conductances (Dürr, V. and Egelhaaf, M., 1999; Kurtz, R. *et al.*, 2001). Based on experimental and modeling studies, the latter adaptation measure has been proposed as a general mechanism applied in many species across phyla (e.g., Wang, X. J., 1998; Gabbiani, F. and Krapp, H. G., 2006).

In functional terms the work by Harris R. A. *et al.* (2000) is of particular significance regarding optic flow processing and the estimation of self-motion parameters. If the entire population of LPTCs is used to estimate self-motion parameters, all the cells are required to be in the same adaptational state. Nondirectional mechanisms would, in a first approximation, affect each LPTC of the population in about the same way (ibid).

1.06.3.1.3.(viii).(c) Local adaptation phenomena Besides one report in the 1980s (Maddess, T. and Laughlin, S. B., 1985), a few more recent studies addressed the spatial aspect of motion adaptation in spiking H1 and V1 cells. Neri P. and Laughlin S. B. (2005) found adapting stimuli moving in the antipreferred direction to increase the directional gain at a neighboring, but nonadapted position within the cells' receptive fields. This result did show that

local information about the adaptational state of the cell is spatially spread to other areas in the receptive field. Such mechanism could overcome the problem that visual scenes consisting of a patchy contrast distribution may result in an anisotropic adaptational state across the cell's receptive field. A related study on the local integration properties of LPTCs under different motion adaptation conditions (Neri, P., 2006) revealed evidence for a gain normalization mechanism previously proposed for motion-sensitive neurons in the primate visual system (Heeger, D. J. *et al*., 1996; Simoncelli, E. P. and Heeger, D. J., 1998).

Most of the physiological mechanisms underlying the spectrum of motion adaptation and gain control phenomena are not as yet understood. Nonetheless, it is obvious that any successful estimation of self-motion parameters the LPTCs perform critically depends on preventing the cells' output range from saturation and on a similar adaptational state of all members of the population.

1.06.3.1.3.(ix) Quantitative behavioral studies and electrophysiological replay experiments One of the major issues in studying motion-sensitive neurons is that most of the studies so far were carried out under laboratory conditions and using rather artificial motion stimuli. While such systems analysis approach revealed invaluable results regarding the functional organization of motion vision pathways, it does not allow us to directly infer their performance under natural conditions. Furthermore, electrophysiological experiments have to be performed under conditions where the animal is fully restrained and not able to move at all, otherwise, in particular stable intracellular recordings would not be possible. This, however, means that the action–perception loop (Figure 1) is not closed any more. The consequence is a situation for the animal that is fundamentally different from what it would experience under natural conditions. There are two key differences: (1) while in freely moving animals self-motion results in optic flow, within the entire 4pi visual field most laboratory stimuli were considerably smaller in size. (2) Many laboratory stimuli were designed to mimic particular movements of the animal. However, the actual combination of translation and rotation that a freely moving animal experiences in a specific visual environment was not very well defined. The latter point is particularly important since translation-induced optic flow depends on the distance between the animal's eyes and the visual objects in the surroundings (cf. eqn [1]).

Only a few years ago the so-called replay experiments (rev.: Heisenberg, M. and Wolf, R., 1993) were introduced into the combined behavioral, electrophysiological, and modeling research on insect vision (Kern, R. *et al*., 2000). Reply experiments partly address the limitations of artificial stimuli. They involve several steps: First, a video system monitors the trajectory of a freely moving animal in a well-defined visual environment. Second, from the animal's trajectory, the self-motion parameters are obtained, which – knowing the visual surroundings – are used to reconstruct the optic flow the animal has experienced. Finally, the reconstructed optic flow sequence is presented to animals during electrophysiological experiments while recording the activity of LPTCs and the resulting data may be correlated with the known self-motion parameters.

In a detailed behavioral analysis it was found that monocularly blinded flies walk along trajectories that balance translatory and rotatory optic flow (Kern, R. and Egelhaaf, M., 2000). This way the animals minimize the net difference between perceived retinal image shift over the left and the right eye to obtain an optomotor equilibrium (Götz, K. G., 1975). The first replay experiments used a computer monitor to present HSE cells with optic flow sequences reconstructed from average fly walking trajectories (Kern, R. and Egelhaaf, M., 2000). The electrophysiological results in combination with model simulations supported the conclusion that monocularly blinded flies try to keep their optomotor in equilibrium (Kern, R. *et al*., 2000). Further replay experiments were based on trajectories obtained from flies walking in an arena that contains obstacles. These experiments produced some interesting results regarding the coding of angular velocities in HSE cells. All angular velocities greater than $\pm 50^\circ$ per second changed the HSE membrane potential to the same level of depolarization/hyperpolarization, respectively. Within the intermediate range the HSE responses and the angular velocity were linearly related with an extremely steep slope. This result was found to be independent of the specific 3D layout of the surroundings (Kern, R. *et al*., 2001).

For further replay experiments, a highly sophisticated visual stimulator, flimax, was used (Lindemann, J. P. *et al*., 2003). Flimax consists of several thousand individually controllable light-emitting diodes (LEDs) altogether approximating about three quarters of the fly's spherical visual field. A spatial resolution below 1° per LED in combination with a fast control of light intensities made flimax (Lindemann, J. P. *et al*., 2003) more versatile than previous wide-field stimulation devices (e.g., Karmeier, K. *et al*., 2003).

Most recently another major finding was made in the context of processing optic flow information in fly LPTCs. Once again, quantitative behavioral experiments did build the foundation of a series of studies on new ideas about what parameters LPTCs encode. Using search coils small enough to be mounted on head and body of blowflies positioned in perpendicular magnetic fields, Schilstra C. and van Hateren J. H. (1998) monitored the animals' head and body movements at a continuous temporal resolution. This way an enormous body of semifree flight data was accumulated while the flies negotiated a cubicle of 0.4 m edge length (Figure 11(a)). A detailed analysis of the data produced not only the flight envelop of the insect but also a continuous monitor of the animals' head movements in space, which ultimately determine the optic flow it experiences. It was discovered that the flies generated a repetitive pattern of characteristic flight sequences: Short rapid saccades were followed by intervals of drifting translations, most likely the result of inertia, which were followed again by another saccade. The direction of the saccades was always away from the wall that was closest to the animal (van Hateren, J. H. and Schilstra, C., 1999). Like humans and many other visually oriented animals, flies keep their eyes aligned with the external horizon and also use fast head movements to minimize the time period during which rapid rotations cause motion blur and degrade visual processing (ibid).

Knowing head and body position at any point in time as well as the exact environmental layout allowed Kern R. *et al.* (2005) to model the fly movements in minute detail (Figures 11(b) and 11(c)). From these data, sequences of optic flow were calculated and, using flimax, were presented to flies in replay experiments while recording the activity of the HSE cell (Kern, R. *et al.*, 2005; van Hateren, J. H. *et al.*, 2005). A subsequent coherence analysis between the self-motion parameters and the HSE responses suggested that this cell serves to indicate not only yaw rotations around the vertical axis but also translation parameters. Depending on whether the sum or the difference of the HSE cell activities from the left and the right lobula plate was taken into account, either thrust or sideslip could be estimated as well (Figures 11(d) and 11(e)). This finding suggests a double function of the HSE cell: During saccadic flight intervals the neuron may encode yaw rotation while it indicates sideslip translation during the drift phases. A parsimonious model of the fly motion vision pathway did capture these new electrophysiological results (Kern, R. *et al.*, 2005).

That the HSE cells are also involved in assessing translation parameters opens up another possible way of exploiting optic flow: that is, to estimate relative distances – a notion that goes back to Gibson's J. J. (1950) accounts on the ecological aspects of optic flow. Comparing the activity level between HSE cells from both sides of the brain during translational drifts allows the animal to sense at which side objects in the visual field are closer. Based on this information the fly can decide in which direction the next saccadic turn should take place to avoid collision with any objects around (Kern, R. *et al.*, 2005; van Hateren, J. H. *et al.*, 2005). Because the magnitude of translational optic flow depends on distance (cf. eqn [1a]), the next turn should always be executed away from the side in which the HSE signal is stronger.

The other interesting conclusion is that flies seem to employ a strategy of active vision to assess distance information from optic flow. It is very likely that the motor program controlling such active vision mode changes depending on the given environment: Confined spaces need a higher frequency of saccades to avoid collision, while in open space when the fly performs cruising flights the saccade frequency may be significantly reduced. It would be very interesting to study the correlation between the fly's flight envelop depending on the distance distribution within the environment the animal is operating in.

An important prerequisite for such elegant active vision strategy to work one head movement. Only if the head is perfectly well stabilized relative to the surrounding by means of compensation for all rotational degrees of freedom a pure translation flow field is perceived useful for distance estimation. Blowflies compensate for roll rotations with a gain of nearly 1 employing a variety of sensory mechanisms (rev.: Hengstenberg, R., 1993, see Section 1.06.6.1). Pitch compensation also takes place but is limited by anatomical constraints (ibid). However, for obvious reasons the fly cannot compensate for massive body saccades about the yaw axis by means of head movements. A detailed analysis of the data obtained during semifree flight (van Hateren, J. H. and Schilstra, C. 1999; Schilstra, C. and van Hateren, J. H., 1999) shows flies to pursue a certain strategy when performing a body saccade around the yaw axis. By means of head movements the animals seem to actively minimize the time during which the head rotates in space. The rapid but shorter rotation phase means that the head is stabilized for a longer period of time to analyze the translation-induced component of optic flow, which are relevant to distance estimation. Minimizing the rotation phase is a

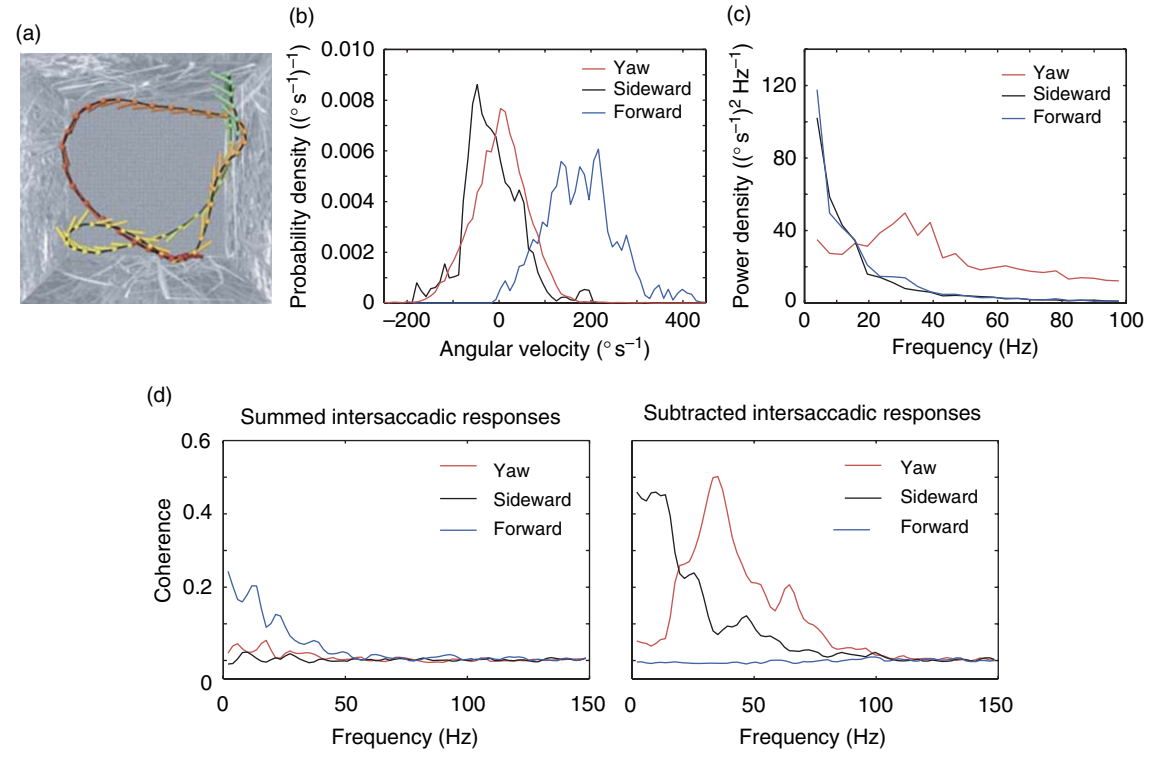

Figure 11 Electrophysiological reply experiments. (a) Reconstruction of a semifree flight trajectory of the blowfly Calliphora as seen from above when negotiating a cubicle of 0.4 m edge length. From such trajectories optic flow sequences were computed and used as stimuli in electrophysiological replay experiments. (b) Probability density of three different motion parameters computed from reconstructed trajectories, yaw (red), forward (blue), and sideslip (black). (c) The power density of the same three motion parameters plotted in the frequency domain. (d) The coherence between yaw rotation, forward translation, and sideslip components in reconstructed optic flow sequences and the responses of the HSE cell. The analysis was carried out for the time interval between two body saccader of the animal. If the activity obtained from the HSE cell in the left brain hemispheres is added to the activity of its counterpart in the right hemisphere the resulting signal shows coherence with forward translation in the low-frequency range (blue line, left panel). If the activity of the two HSE cells is subtracted the signal shows coherence with sideslip translation in the low-frequency range (black line, right panel) and with yaw rotation in the high-frequency range (red line, right panel). For further explanation see text. Adapted from Kern, R., van Hateren, J. H., Michaelis, C., Lindemann, J. P., and Egelhaaf, M. 2005. Function of a fly motion-sensitive neuron matches eye movements during free flight. PLoS Biol. 3, e171.

strategy that humans also apply in coordinated head and eye movements where vision is suppressed altogether (rev.: Carpenter, R. H. S., 1988).

The potential role of HS cells in analyzing translation flow was already discussed (e.g., rev.: Hausen, K., 1984; Krapp, H. G., 2000). The HSS cell, with its ventral receptive field suited to sense translation flow and not receiving rotation-specific contralateral input, was the ideal candidate for analyzing the translation flow in the context of estimating ground speed. However, studies on the distinctly different signal structure that HSE generates in response to approximated rotation and translation stimuli (Horstmann, W. *et al.*, 2000) anticipated as well a potential double function for the HSE cell. The distribution of motion preferences within the cell's receptive field also supports this idea: If analyzed in monocular animals the distribution shows a marked similarity to a translational optic flow field generated during an intermediate between forward motion, that is, thrust, and sideslip. In binocular animals, however, the local preferred directions of HSE and HSN cells, both of which receive rotation-specific contralateral input, reveal a distribution resembling an optic flow field that results from yaw rotation (Krapp, H. G. *et al.*, 2001). This point is interesting since it implies that the organization of local inputs seems to support the double function of the HSE cell. During yaw turns, the rotation flow better matches the cell's binocular receptive field organization. When translating, however, most of the rotation-specific

contralateral input is inhibited, which effectively converts the HSE into a monocular cell with a distribution of local inputs suitable to sense translation-induced optic flow.

In summary, several factors seem to contribute to the separation of rotation- and translation-induced optic flow underlying the double function of the HSE cell in the blowfly: (1) a particular flight pattern, active vision, which separates rotation from translation phases; (2) accurate gaze stabilization that keeps the head in its default orientation and minimizes the time intervals during which rapid rotation impair vision; and (3) the input organization of the HSE receptive field in combination with (4) the cell's differential signal structure. Together these factors allow the HSE to provide optic flow–derived information to be used in two different contexts. Responses during yaw rotations affect inner-loop flight and gaze stabilization while relative distance information may affect the outer-loop control to avoid collisions.

Experiments on freely flying *Drosophila* also suggest that flow field information is used to estimate the distance to the walls in a textured flight arena (e.g., Tammero, L. F. and Dickinson, M. H., 2002). Reconstructing the optic flow that the flies experienced just before they perform a saccade away from the arena wall revealed that pattern expansion seems to be the relevant motion cue. Unfortunately, virtually nothing is known about the neural circuits controlling collision avoidance saccades in *Drosophila* since electrophysiological studies on the central visual system in such a small fly are still extremely demanding. The receptive fields of interneurons involved in triggering the saccades may be differently organized than those of the HSE cells in the blowfly. So far only a few LPTCs have been characterized in the blowfly the receptive field organization of which suggests them to sense expansion patterns (Krapp, H. G. and Hengstenberg, R., 1996; Krapp, H. G. *et al.*, unpublished).

1.06.3.1.4 Self-motion estimation in other invertebrate species

The processing of optic flow information for inner-loop tasks – and also in the context of distance estimation – is obviously not confined to flies. Though not as exhaustive as the data body gathered in the fly visual system a few studies on wide-field directional-selective neurons were also performed in other arthropods. These studies are particularly interesting since they allow us to identify general principles and species-specific adaptations to optic flow processing. Directional-selective wide-field neurons were found in Hymenoptera (Ibbotson, M. R. 2001), Orthoptera (Kien, J., 1974; Gewecke, M *et al.*, 1990; Rind, F. C., 1990; Rind, F. C., 1990), Odonata (Olberg, R. M., 1986), and Lepidoptera (Collett, T. S. and Blest, A. D., 1966; Milde, J. J., 1993; Wicklein, M. and Varju, D., 1999). The presence of such neurons in a variety of insect species and in many vertebrates alike (Lappe, M., 2000) indicates that the analysis of optic flow is a common theme in visual information processing. Detailed information on the receptive field organization in wide-field optic flow neurons, however, is so far available only for a small number of flying insects other than blowflies (hoverflies: Straw, A. D. *et al.*, 2006; locusts: Wüstenberg, D. and Krapp, H. G., 2007) and crabs (Johnson, A. P. *et al.*, 2002).

1.06.3.1.5 Open questions

Our understanding of directional motion processing in insects has been significantly improved over the past three decades or so, thanks to the combination of quantitative behavioral experiments, electrophysiological, and modeling studies. In particular in the fly, key discoveries were made including the detailed organization of the LPTC receptive fields and their adaptation properties, the ipsilateral and heterolateral network interactions, as well as the suggested role of HS cells in estimating the distance to objects in the surroundings. These findings should help to refine our experimental efforts and to develop new concepts in visuomotor control. HS cells and probably VS cells, too, may contribute not only to inner-loop control tasks such as gaze and flight stabilization control, but also to collision avoidance, a typical outer-loop task. How does the fly nervous system integrate outer- and inner-loop control without compromising the respective function? Do flies use forward models or efference copies to tell apart rotation- and translation-induced LPTC signals? Where does the integration of visual information and signals from other sensory systems, also contributing to inner- and outer-loop control, take place? And finally, how is the information provided by LPTCs decoded at the next processing level to achieve an appropriate sensorimotor transformation?

From the methodological point of view, replay experiments were certainly an important step forward. Nonetheless, they still do not solve the problem that during replay experiments the animals are not in a natural closed-loop situation and have no access to information from sensory systems other than the compound eye (Kern, R. and Egelhaaf, M., 2000). Also, replay experiments depend strongly on

the availability of behavioral data obtained in freely moving animals. Current behavioral data may not reflect the entire range of self-motions that an animal would be able to perform if there were no spatial constraints. The greatest challenge for future research will be to design experimental approaches, which will allow us to record the activity in freely or at least in semifreely behaving animals. Some efforts on insects bigger than the fly are on its way to achieve this goal as electric circuits are now being miniaturized and radio transmission of sufficient bandwidth become available to log the data. But still, neural recording data will help us to further our understanding of general principles in visual information processing only if they are correlated with the sequences of optic flow that the animals experienced while moving.

1.06.3.2 Responding to Motion from the Outside World – Visual Information Controlling the Outer Loop

Inner-loop reflexes such as gaze and flight stabilization are meant to provide the basic requirements for any purposeful behavior, that is, to keep the retinal image in its default orientation, to facilitate sensory processing, and to maintain stable posture or locomotion. As mentioned earlier the systems controlling these two tasks need to be modified whenever the animal intends to perform a goal-directed task. Otherwise it would be trapped forever in its inner-loop reflexes. In the following we will outline a few examples of visually guided behaviors and their underlying neural processing, which, to be accomplished, require a modification of the inner-loop control. Many of these tasks exploit motion cues that are selectively integrated to support behaviors including object detection, chasing, preying, collision avoidance during swarming, escape, and landing.

Although any retinal image shift per definition has a direction, depending on the task the visual system may or may not require directional information to control it. For instance, stabilizing a target on the frontal retinal works perfectly well in a closed-loop situation when a sinusoidal transfer function relates the instantaneous retinal position to a turning response toward the target (e.g., Boeddeker, N. and Egelhaaf, M., 2003, see Section 1.06.3.2.1.(i)). A similar parsimonious strategy would also work to intercept a target. In this case, if a constant retinal target bearing is maintained by only adjusting thrust, interception eventually occurs (Collett, T. S., 1980; Olberg, R. M. *et al.*, 2000).

The benefit of any nondirectional detection mechanism is quite obvious: Computing the direction of motion always takes some extra time due to the delay filter in the EMD (see Section 1.06.3.1.2). Sensing and integrating nondirectional motion certainly works faster and is probably the default strategy when responses on the millisecond timescale are vital to survive. Interestingly, despite the obvious time constraints in controlling some of the behaviors mentioned above the visual system may combine directional and nondirectional motion information. In this section we will concentrate on a few selected examples where – at least partly – a specific behavior can be explained by its underlying neural mechanisms.

1.06.3.2.1 Chasing females and prey

Among flying insects, chasing comes in two behavioral contexts: mating and preying. In both cases the detection of comparatively small targets is required (see Section 1.06.3.2.3) followed by high-speed chasing maneuvers, which, if successful, culminate in mating or hitting prey.

1.06.3.2.1.(i) Chasing female flies In several insect species, chasing behavior is supported by conspicuous sexual dimorphisms (e.g., rev.: Land, M. F., 1997; Land, M. F. and Nilsson, D. E., 2002). Ommatidia arranged in the frontal to frontodorsal eye region of some male flies are equipped with bigger lenses (e.g., Stavenga, D. G. *et al.*, 1990) and sample the visual space at higher spatial resolution (e.g., Land, M. F. and Eckert, H., 1985). Male photoreceptors in that region are faster and significantly more efficient in detecting small moving objects (Hardie, R. C., 1983; Hornstein, E. P. *et al.*, 2000; Burton, B. G. *et al.*, 2001; Burton, B. G. and Laughlin, S. B., 2003). In the lobula, wide-field neurons integrate motion information in a sex-specific way. Individually identified male lobula giant (MLG) interneurons (Hausen, K. and Strausfeld, N. J., 1980) are either underdeveloped or even missing altogether in females. For obvious reasons there is massive evolutionary pressure on males to excel in a discipline that requires fitness in all departments and the results of which are so immediately turned into offspring, the hard currency of evolution.

There are two other points that should be mentioned before outlining in more detail what chasing

behavior in blowflies typically looks like. First, high-speed chasing in flies at close range purely depends on vision – no other long-range modality such as olfaction would be able to provide information quickly enough to control such aerobatic directional changes, which easily exceed angular velocities of 3000° per second. Second, chasing really needs to be efficient since it consumes energy spent not only on the flight motor but also on the sensory processing. Though the specialized photoreceptors in males, for instance, are way better tuned to the task than their female counterparts this comes at the cost of greater energy consumption (Laughlin, S. B., 2001; Burton, B. G. and Laughlin, S. B., 2003).

Early work suggested different control mechanisms being involved in chasing: A mechanism analog to the one controlling smooth pursuit eye movements in humans (Land, M. F. and Collett, T. S., 1974; Wehrhahn, C. *et al.*, 1982; Land, M. F., 1993) and a saccadic mechanism (Wagner, H., 1986) similar to the one that humans employ when trying to catch up with fast moving objects (e.g., Robinson, D. A., 1968; rev.: Carpenter, R. H. S., 1988). The analogy between eye movements in humans and chasing in flies is justified by their common function: Both human eye movements and chasing serve to stabilize a moving target on a certain retinal positions, that is, the fovea in humans and the area of highest spatial resolution concerned with chasing in flies, called the love spot. (Land, M. F. and Eckert, H., 1985).

In recent studies, male blowflies were video-taped while tracking dummy flies moved along a circular path. The observed trajectories did fall into two classes: Either the flies do catch the target (Figure 12(b), left) or the flies do not catch it but instead chase the target for several consecutive cycles (Figure 12(b), right). A detailed analysis of the data revealed a control system that takes into account the target's retinal position and size (Figure 12(a)). Whether the fly caught the target or not did depend on the speed and size of the dummy. Increasing the target speed or the size reduced the number of flights in which the male fly actually reached the dummy (Boeddeker, N. *et al.*, 2003).

Based on the experimental data a phenomenological model was derived, which, despite its parsimonious design, could explain the bistable distribution of chasing flights (Boeddeker, N. and Egelhaaf, M., 2003). Inputs to the model were retinal position and size of the target, which were transformed into two output variables, turning velocity and forward velocity, processed in two different

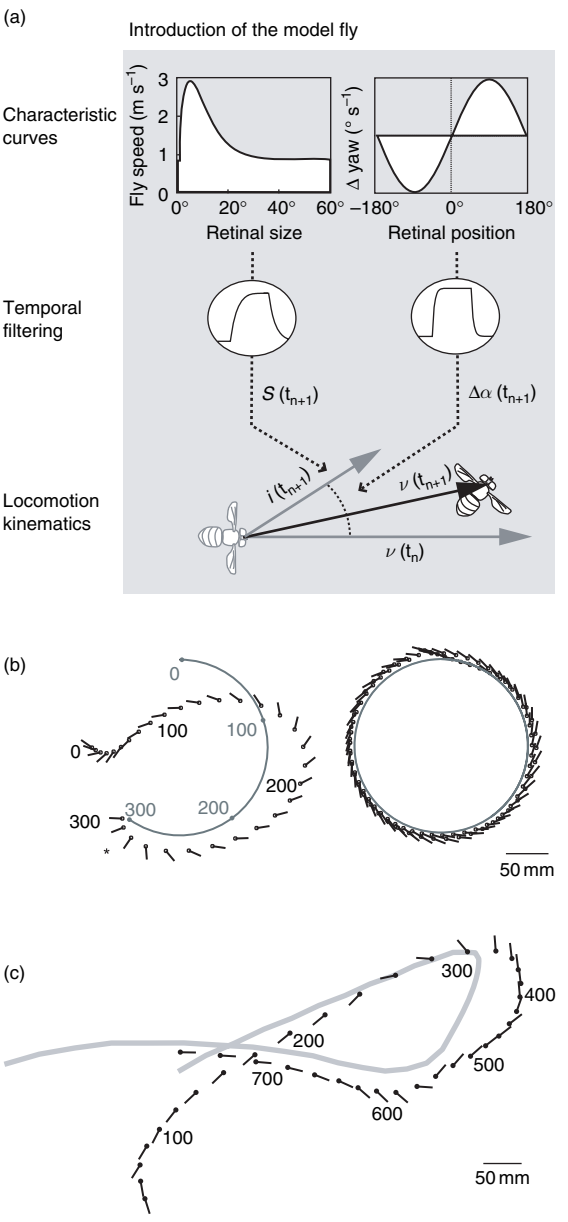

Figure 12 Chasing in male blowflies. (a) The relationship between thrust and yaw velocity, retinal size, and position of the target (upper panels), and the temporal filters (lower panels) used to model chasing flights in the blowfly *Lucilia*. The lower drawing illustrates the flight kinematics. (b) and (c) The model predicts chasing trajectories where the fly catches a dummy fly (b, left) and where it follows the target on a circular path for several consecutive rounds (b, right), but also situations where the leading fly performs more complex flight maneuvers (c). For further explanations see text. Adapted from Boeddeker, N. and Egelhaaf, M. 2003. Steering a virtual blowfly, simulation of visual pursuit. Proc. Biol. Sci. 270, 1971–1978; Boeddeker, N. and Egelhaaf, M. 2005. A single control system for smooth and saccade-like pursuit in blowflies. J. Exp. Biol. 208, 1563–1572.

pathways. (1) The thrust control did depend on retinal target size in a nonlinear way. For target sizes below 0.5° and above 20° the forward speed was set to a default value. In between it depended on the target size in an exponential way with a maximum thrust at about 5°. (2) The turning response of the fly toward the target was related to the target's retinal position by a sinus function with a zero crossings in front and behind the fly (Figure 12(a)).

The behavioral data suggested that the outputs of these pathways were differently delayed before affecting the flight trajectory, either due to latencies in neural processing or because of the low-pass properties of the motor system (Boeddeker, N. *et al.*, 2003). The delays were implemented by applying a 15-ms low-pass filter to the position-dependent and an 80-ms low-pass filter to the size-dependent motor commands, controlling rotation and forward velocity, respectively (Figure 12(a)).

The forces acting on flies flying under unsteady aerodynamic conditions (e.g., Dickinson, M. H. *et al.*, 1999; Ellington, C. P., 1999; Frye, M. A. *et al.*, 2003) in relation to its inertia were only approximated. The degree to which kinematics caused a difference between intended and actually flown velocities was a free parameter used to fit the model trajectories to those observed during the behavioral experiments.

In a follow-up account Boeddeker N. and Egelhaaf M. (2005) did show that their model also predicts features of male flies chasing females on a natural trajectory (Figure 12(c)). More realistic chasing flights did show a higher frequency of rapid, saccade-like turns even though saccadic turns were not explicitly implemented in the control structure. The saccade-like turns were interpreted as a consequence of different processing delays in the position and distance controller pathways in combination with the inertia of the chasing fly when applied to more complex trajectories of the leading fly (Boeddeker, N. and Egelhaaf, M., 2005).

The Boeddeker N. and Egelhaaf M. (2003; 2005) model is an excellent example to make an important point: Seemingly complex behavioral variants, either catching or pursuing a fly, are readily explained by a simple set of rules. When applying the rules under closed-loop conditions in an environment that approximates the laws of physics, two different behavioral outputs result. No explicit decision-making algorithm is required to produce either of the two behavioral traits. It is just a threshold angle on the retina in combination with a long time constant in the path of the control system computing forward velocity. This design also prevents the chasing fly from catching targets too big to be conspecific females – another useful feature for obvious reasons. And finally, the system's inherent properties nicely explain that during chases both saccade-like and smooth pursuit sections occur simply by approximating fly kinematics and without assuming a saccade controller (ibid). What the model does not take into account, however, is the question of how chasing control interacts with the inner-loop optomotor reflexes which some of the earlier studies did (e.g., Collett, T. S., 1980).

Casing behavior is meanwhile well characterized in several species and has inspired a number of models describing its possible control structure. How much do we know about the neural pathways controlling the behavior? Although sex-specific specializations at the level of the photoreceptors in the compound eye's love spot were conclusively demonstrated (e.g., Hornstein, E. P. *et al.*, 2000; Burton, B. G. *et al.*, 2001; Burton, B. G. and Laughlin, S. B., 2003), the underlying neural mechanisms working at more central stages are less well-known. The response properties of MLG interneurons (Hausen, K. and Strausfeld, N. J., 1980) and their postsynaptic targets conveying information to various motor systems were investigated only in a few studies (Gilbert, C. and Strausfeld, N. J., 1991; Gronenberg, W. and Strausfeld, N. J., 1991). Two MLG neurons, MLG1 and MLG2, seem to respond to motion in a directional-selective manner, though the electrophysiological data are mostly based on individual recordings. Other MLGs and their postsynaptic descending neurons were found to be sensitive to nondirectional motion of small objects (ibid). So far, our knowledge about the electrophysiological response properties of MLGs is in contrast to their solid neuroanatomical description. The latter includes the neurons' dendritic and terminal arborizations in parts of the lateral protocerebrum and different segments of the thoracic ganglia (ibid). By combining anatomical data and electrophysiological results, Gronenberg W. and Strausfeld N. J., (1991) proposed a putative circuit involved in chasing behavior. The model includes pathways devoted to the control of forward and yaw velocity – in a way supporting the design of the Boeddeker N. and Egelhaaf M. model (2003). Later studies confirmed directional-selective responses in MLG1 and MLG2 (Wachenfeld, A. and Hausen, K., 1994). Wachenfeld A. and Hausen K. (1994) suggested the function of these MLGs to be involved in controlling retinal target position during the chase

before the fly boosts its thrust for the final catch. This would mean that MLGs participate in both neural pathways Boeddeker N. and Egelhaaf M. (2003) suggest, though neither of these pathways explicitly requires directional motion information.

In summary, fly chasing remains an area where several questions still await answers. Besides the lack of conclusive electrophysiological data, one of the questions concerns the fundamental problem we already mentioned above that all motor control systems face: How does the system avoid being trapped in its inner-loop reflex control? Von Holst E. and Mittelstaedt H. (1950) put forward this question already more than 50 years ago. But in the work on insect vision, surprisingly few researchers did address this problem. Successful chasing behavior clearly requires the outer-loop control system to modify the operation of the inner-loop flight stabilization reflexes (e.g., Collett, T. S., 1980; rev.: Heisenberg, M. and Wolf, R., 1993; Chan, W. P., *et al.*, 1998). Switching off the reflexes altogether would be no viable option since to successfully complete any goal-directed behavior the control of posture and attitude are necessary prerequisites – as is gaze stabilization, without which none of the behaviors would work properly.

1.06.3.2.1.(ii) Catching prey on the fly – aerial predators' visual hunting strategies Prey catching during flight has been successfully investigated in dragonflies – for obvious reasons: Dragonflies of the family Aeschnidae possess an unbeatable number of 28 000 ommatidia per compound eye (Sherk, T. E., 1978), endowing these aerial predators with a – for insect standards – superb spatial resolution well below 1°. Most dragonflies show conspicuous anatomical specializations of their frontodorsal eyes designed to detect potential prey against the blue sky (e.g., Labhart, T. and Nilsson, D. E., 1995). The flight envelop of dragonflies, the combination of possible translations and rotations, is as impressive as is their peripheral visual system. Some species reach translation velocities of up to $10\,m\,s^{-1}$ and are capable of performing acrobatic flight maneuvers as spectacular as the Immelmann turn (Taylor, G., unpublished data). Its nearly perfect adaptation to aerial hunting makes the dragonfly a truly rewarding experimental model system to study the neural mechanisms underlying the detection and chasing of airborne prey.

Other than in the field of directional motion vision (see Section 1.06.3.1.2), the research on prey catching in dragonflies started with electrophysiological rather than behavioral observations. In the 1980s the response properties of descending neurons were investigated connecting protocerebral areas with different thoracic ganglia. These descending neurons could be grouped into multimodal large-field descending neurons, thought to mediate information about panoramic image shifts, and small-field descending neurons responding best to the movement of small visual stimuli. Because of their tuning to a certain visual feature, namely the movement of small objects, the latter group was termed target-selective descending neurons (TSDNs) (Olberg, R. M., 1986). Studies on cells in the dragonfly lobula complex, presynaptic to the descending neurons, revealed two types of feature detectors: small target-sensitive cells responding in a directional-selective way to motion and cells tuned to a specific orientation of a small elongated bar (O'Carroll, D. C., 1993). The response properties of small target-sensitive and bar-sensitive cells in the dragonfly did show a striking similarity to those of hypercomplex and simple cells in the mammalian visual cortex (O'Carroll, D. C., 1993; cf. Hubel, D. and Wiesel, T. N., 1962). This finding once again underlines similar principles in visual scene analysis across phyla when it comes to extracting specific features.

Further studies assessed the receptive field organization of TSDNs, probably the targets of lobula complex cells (Frye, M. A. and Olberg, R. M., 1995). Descending neurons of the medial dorsal tract and the dorsal intermediate tract were found to have receptive fields directed toward the frontal to frontolateral visual field above the external horizon (Figure 13(a)). Thus, these descending neurons most likely receive input from the compound eye region specialized for prey detection (Labhart, T. and Nilsson, D. E., 1995). The receptive field size of the TSDNs varied from about 40° to 90° in diameter. Some of them responded better to the motion of black squares of either 4° or 16° edge length, others were sensitive to both stimulus sizes. Most TSDNs were directionally selective. They preferred horizontal motion or vertical motion and, in some cases, intermediate components at certain locations within their receptive field (Frye, M. A. and Olberg, R. M., 1995).

Based on the electrophysiological data the TSDNs were hypothesized to play an important role in prey catching. It was not clear, though, which strategy dragonflies prefer during their aerial hunts. Collett T. S. and Land M. F. (1978) had earlier suggested two different strategies, which were observed in the general context of chasing behavior, tracking or intercepting

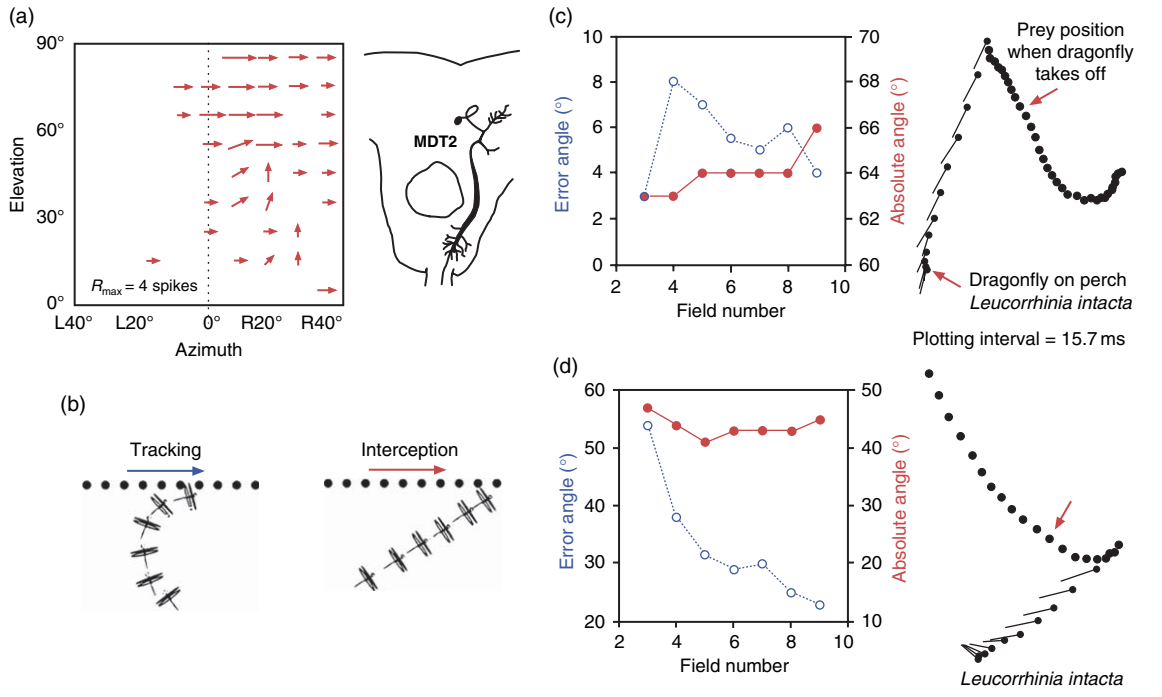

Figure 13 Target-selective neurons in the dragonfly. (a) Receptive field and reconstruction of the median dorsal tract neuron 2. The neuron responded in a directional-selective way to small black squares of 4° edge length presented in the frontal to frontolateral parts of the dorsal visual field (arrows, left panel). (b) When hunting dragonflies could either track or intercept potential prey (after Collett, T. S. and Land, M. F., 1978). For further explanation see text. (c, d) Dragonflies when detecting prey orient themselves toward the potential prey and approach nearly on a straight line. Left panels show the error angle (open blue symbols) and the absolute angle (filled red symbols) plotted against consecutive video frames (field number). The dragonflies achieve interception by adjusting thrust, so that the target's absolute angular position on the retina is kept constant. For further explanation see text. Redrawn from Frye, M. A. and Olberg, R. M. 1995. Visual receptive-field properties of feature detecting neurons in the dragonfly. J. Comp. Physiol. A Sens. Neural Behav. Physiol. 177, 569–576; Olberg, R. M., Worthington, A. H. and Venator, K. R. 2000. Prey pursuit and interception in dragonflies. J. Comp. Physiol. A 186, 155–162.

(Figure 13(b)). When tracking, the chasing animal aims to minimize the angle between its frontal visual field and the target's position on its retina. The result is a curved flight trajectory where the chasing animal spirals in on the target. Intercepting is controlled in a different way. In this case the retinal position of the target is kept constant by adjusting only the thrust, given the target position is within the frontolateral visual field. This strategy produces a fairly straight flight trajectory that eventually results in intercepting the target. Most insects track rather than intercept, whether it is tiger beetles hunting on the ground (Gilbert, C., 1997), male flies chasing females (e.g., Collett, T. S. and Land, M. F., 1975a; 1975b; Wagner, H., 1986; Land, M. F., 1993; Boeddeker, N. *et al.*, 2003), or honeybees tracking moving targets (Zhang, S. W. *et al.*, 1990).

A couple of years ago, Olberg R. M. *et al.* (2000) videotaped and quantified free-flight behavior in dragonflies to find out which strategy they employ during aerial hunts. Some dragonflies, such as *Erythemis simplicicollis* and *Leucorrhinia intacta*, are sit-and-wait predators. Most conveniently they select and keep a specific landing site to sit on when waiting for prey and return to it after they completed a hunting trip. Olberg R. M. *et al.* (2000) analyzed the behavior of these species in detail. Once potential prey appears in their visual field, the dragonflies perform some head movements and movements of the body, presumably to prepare for an appropriate take-off orientation, and then approach the prey on a straight trajectory (Figures 13(c) and 13(d)). In 97% of all attempts, the dragonflies were successful in catching the prey. This study quite clearly shows that dragonflies intercept rather than track their prey (Olberg, R. M. *et al.*, 2000). But it also raised the question of how dragonflies distinguish between big birds flying at greater distance and small insects flying past in close range, both of

which may assume the same angular size on the retina? The dragonflies took off only for small insects. The difference between the two situations was the distance and the angular velocity profile of the objects moving across the eye. The close-by prey generated a much more pronounced angular velocity peak on the dragonfly's eye than a distant bird did. This peak in perceived angular velocity was assumed to trigger the hunting flights (Olberg, R. M. *et al.*, 2000). Later work, however, suggests that the dragonfly might also use distance cues.

Further behavioral studies on *Libellula luctuosa* and *Sympetrum vicinum*, both perching hunters as well, demonstrated how accurately dragonflies are capable of discriminating between different target sizes (Olberg, R. M. *et al.*, 2005). Using glass beads of diameters between 0.5 and 0.8 mm as dummy prey revealed that both species would only launch a catching flight if the absolute size of the potential prey did not exceed the dragonflies' head diameter. Olberg R. M. *et al.* (2005) concluded that neither retinal size nor angular velocity of the target alone triggers takeoffs. Only within a preferred distance range a specific angular size initiated the behavior (ibid). What vision-based mechanism might underlie such discrimination task?

Two visual mechanisms potentially allow for distance estimation: motion parallax and stereopsis. Exploiting motion parallax to estimate distance is quite common (rev.: Srinivasan, M. V., 1993; Srinivasan, M. V., and Zhang, S. W., 2000). This possibility becomes immediately obvious from revisiting eqn [1] showing that the magnitude of the local parallax vectors, $\mathbf{p}_i$, is inversely proportional to the distance, D_i – but only for translational movements (Figure 14(c)). Therefore, it is not surprising that several insects actually perform so-called peering movements to induce motion parallax (e.g., locust: Wallace, G. K. 1959; Collett, T. S., 1978; grasshopper: Eriksson, E. S., 1980). The other mechanism, stereopsis, is based on the disparity between the different images seen by the two eyes. It requires an area of binocular overlap and sufficient spatial separation of the eyes – which makes it a common means of distance estimation in many vertebrates including humans (e.g., Rogers, B. and Graham, M., 1982). Despite the small separation of their eyes, even in insects, stereopsis was shown to be used for distance estimation, mainly in the context of preying (e.g., beetle: Bauer, T., 1981; mantis: Rossel, S. 1983; Walcher, F. and Kral, K., 1994, and – not too surprisingly – in dragonfly larvae: Baldus, K., 1926).

Adult dragonflies seem to combine motion parallax and stereopsis to estimate distance, which is a necessary condition for their ability to discriminate between different prey sizes (Olberg, R. M. *et al.*, 2005). How the perching dragonflies exactly perform peering movements to induce motion parallax while still sitting on the perch is not exactly clear yet. Head movements the animals perform upon prey detection usually have a strong rotational component and would therefore not allow for distance estimation (cf. eqn [1a], rotational term). If dragonflies, however, would compensate for the rotational component by simultaneously changing their body orientation, they could achieve a pure translation movement (rev.: Collett, T. *et al.*, 1993).

In summary, at least part of the exceptional dragonfly chasing behavior may be explained by the response

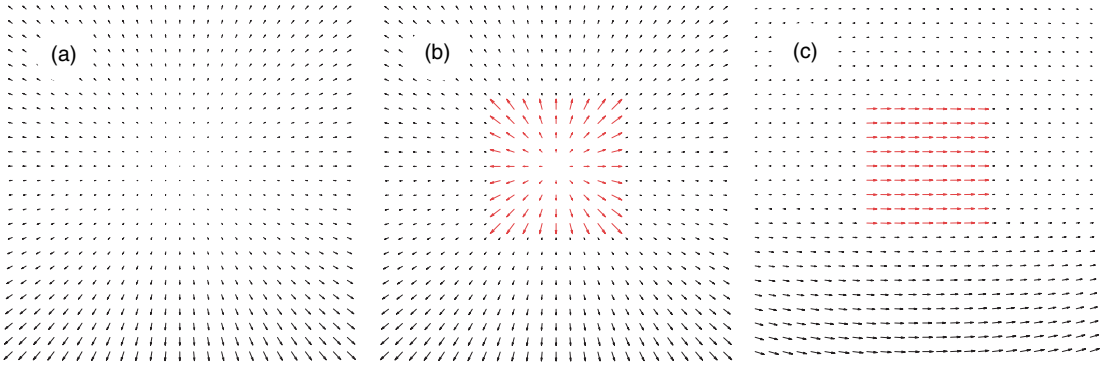

Figure 14 Further properties of translation-induced optic flow. (a) Translation-induced optic flow field, pure thrust, in an asymmetric environment with smaller distances to visual structures below the equator. A translation flow field has a focus of expansion, which, during pure translation, identifies the heading direction. (b) Same background flow field but with an object close in front. The object casts a looming pattern (red arrows) of object expansion, which is due to the closer distance to the object than to the background. (c) Side-wise translation induces motion parallax, which is also based on the difference between the distance to the object and to the background. All flow fields were computed using eqn [1].

properties of identified TSDNs (Olberg, R. M., 1986; O'Carroll, D.C., 1993; Frye, M. A. and Olberg, R. M., 1995). It is still not clear, though, how the different mechanisms involved in estimating distance and size of the potential prey work together with the animal's aerial intercepts to orchestrate all its actions resulting in a remarkable 97% of successful catches. Tough employing a different strategy to catch their prey, i.e., intercepting, they face the same problem as flies do when catching females: the inner- and outer-loop activity needs to be coordinated. There is also a need of conceptual and eventually mechanistic models, which integrate the different steps along the catching behavior with the inner-loop control of gaze and flight stability.

1.06.3.2.2 Discriminating small objects from the background

In dragonflies, takeoff is triggered by targets assuming retinal angles as small as 0.1° to 0.2° (Olberg, R. M. *et al.*, 2005). The smallest interommatidial angles, however, are only in the range of about 0.5° (Horridge, G. A., 1978). Small target detection is often supported by regional specializations of the eyes including anatomical and physiological adaptations. Photoreceptors in dragonflies, for instance, exploit the short wavelengths in the UV range (Laughlin, S. B., 1976; Laughlin, S. B., and McGinness, S. 1978; Labhart, T. and Nilsson, D. E., 1995; Yang, E. C. and Osorio, D., 1996), which increases spatial resolution in particular when targets are discriminated against the blue sky (rev.: Land, M. F. and Nilsson, D. E., 2002). Other flying insects, however, may operate in habitats composed of cluttered visual structure where the contrast between a potential target and the background is considerably reduced. What is the neural basis of such stunning target detection mechanisms?

Another good model system to demonstrate the remarkable ability to detect objects smaller than the compound eye's spatial resolution is the hoverfly *Eristalis*. These animals stabilize their flight to remain in a comfortable sunlit spot and defend this spot against any potential intruders – conspecific males or others – while waiting for females to pass by. Detecting a potential target triggers a sequence of events that starts with computing an interception course based on the target angular position and velocity on the hoverfly's retina (Collett, T. S., and Land, M. F., 1978). Hoverflies are less picky than dragonflies and can be easily persuaded to dart at targets, which do not fall into the size and speed range of conspecifics – in which case the effort will obviously remain unsuccessful given it was a female the hoverfly was after. Possible assumptions about size and speed of conspecifics were thought to be innate and, together with knowledge about its own speed, confine the animal's successful computation of intercept trajectories to other hoverflies (ibid). Once the trajectory is computed the outcome defines the magnitude of an initial rotation about the vertical axis, which sets the direction of the intersecting flight (ibid). The computation of the magnitude of this initial rotation and its execution are equivalent to the computation and the performance of catch-up saccades observed in primate eye movements (e.g., Robinson, D. A., 1973).

After the rotation the hoverflies perform a ballistic, open-loop acceleration along a straight path, which gets them close to the target. Then a closed-loop chasing controller takes over and governs the final flight sequence (Collett, T. S. and Land, M. F., 1978) which is probably comparable to the one blowflies employ (Boeddeker, N. and Egelhaaf, M., 2003, see Section 1.06.3.2.1).

The success of this behavior depends on an accurate detection of the target since target position is a critical parameter in the computation of the interception course. As mentioned, for hoverflies living in cluttered environments, this is a particularly challenging task. Recent electrophysiological studies discovered an extraordinary contrast sensitivity in small target motion detectors (STMDs) of the hoverfly lobula and lobula plate, which are tuned to the motion of tiny objects (Nordström, K. *et al.*, 2006).

Most STMDs were found to have receptive fields directed toward the frontal to frontolateral visual field above the eye equator (Nordström, K. *et al.*, 2006). Thus, at least part of the local elements STMDs receive signals from are supplied by the eye's bright zone (*Crysomiya*: van Hateren, J. H., *et al.*, 1989, *Eristalis*: Straw, A. D. *et al.*, 2006), which is equivalent to the love spot in *Musca* and *Calliphora* (rev: Land, M. F., 1997; Land, M. F. and Nilsson, D. E., 2002; see Section 1.06.3.2.1). This region is equipped with facets of increased diameter benefiting light capture (Straw, A. D. *et al.*, 2006). Also, like in *Musca* and *Calliphora*, pooling signals from all eight photoreceptors rather than only six in other eye regions increases the signal-to-noise ratio in the postsynaptic lamina cells (e.g., Franceschini, N. *et al.*, 1981; Hardie, R. C., 1983).

A detailed analysis revealed that most STMDs respond to motion of small objects in a directional-selective way (Nordström, K. *et al.*, 2006). Only a few nondirectional-selective STMDs were found as well (Figure 15). In some cases the motion stimuli were

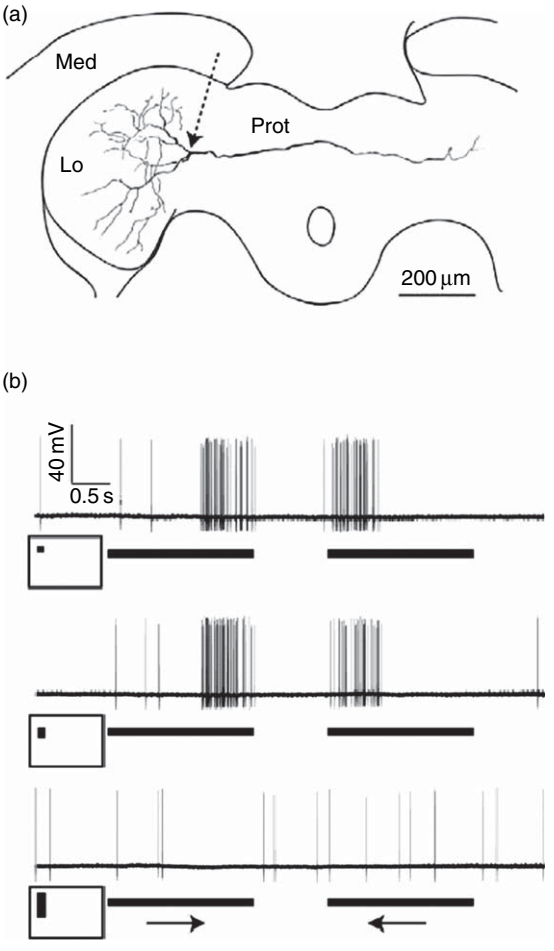

Figure 15 Small target detection in the hoverfly. (a) Reconstruction of a small target movement detector. (b) Intracellular recording traces. The neuron responds most strongly to nondirectional motion of a small bar of $0.8° \times 3.0°$ horizontal x vertical extent, respectively. For further explanation see text. Adapted from Nordström, K., Barnett, P. D. and O'Carroll, D. C. 2006. Insect detection of small targets moving in visual clutter. PLoS Biol. 4, e54.

much smaller than the smallest interommatidial angles measured in hoverflies (Straw, A. D. *et al.*, 2006). Taking into account the optical properties of the compound eye, objects as small as 0.2° in edge length and an effective contrast of only 12% did still produce significant responses in some STMDs (Nordström, K. *et al.*, 2006). Most STMDs did respond even if the object was presented on top of wide-field background motion, irrespective of whether the background was moving at a similar or at the same velocity as the object. Such extraordinary small-field tuning was suggested to depend on extreme contrast sensitivity and on at least two possible inhibitory mechanisms suppressing the response to wide-field motion: for one, a mechanism that involves local spatial inhibition acting at some stage along the peripheral pathway. And secondly, a feedback inhibition, also presynaptic to the STMDs, which may be provided by lobula plate wide-field cells (Nordström, K. *et al.*, 2006).

Studies on a subgroup of small-field STMDs (SF STMDs) in *Eristalis* whose receptive field sizes were only about 8° in diameter suggest that there are spatial limits for background motion-invariant responses (Barnett, P. D. *et al.*, 2007). The retinotopically organized SF STMDs show very similar response properties as their wide-field counterparts (Norström, K. *et al.*, 2006). However, they do not suppress wide-field background motion as efficiently if target and background move at similar or at the same velocity (Barnett, P. D. *et al.*, 2007). The results on both directional-selective and nondirectional-selective small-field and wide-field STMDs may be accounted for – at least partly – by a model for target detection (Higgins, C. M. and Pant, V., 2004). Originally based on the behavioral data obtained in housefly figure-ground discrimination (Reichardt, W. and Poggio, T., 1979), to establish small-field tuning the model incorporates presysnaptic shunting inhibition of local motion signals integrated by an output neuron that controls yaw torque (Reichardt, W. *et al.*, 1983, see Section 1.06.3.1.3.(viii)). The shunting inhibition signals provided by a pool cell are nondirectional-selective. For the model to explain the remarkable small-field tuning of STMDs the local input elements – either directional- or nondirectional-selective – require extreme contrast-sensitivity probably established by horizontal interactions at more peripheral stages (Barnett, P. D. *et al.*, 2007). The reduced invariance against background motion seems to suggest that the receptive field size of the pool cells providing the shunting inhibition signals correspond to the receptive field size of the respective STMDs.

Due to their specific properties, STMDs appear to be perfect candidates to mediate information about both the position and the motion direction of potential conspecifics appearing in the hoverfly's visual field. The way the detection and the subsequent chasing of the target links in with the hoverflies' inner-loop control that stabilizes gaze and flight, though, is yet unknown.

The discrimination between target and background motion is a common problem among visually oriented insects. The way the visual system solves such discrimination tasks, however, seems to depend on the given species. In the blowfly figure detection circuits, both

FD cells and its wide-field inhibitor respond to motion in a directional-selective way (Egelhaaf, M., 1985b, see Section 1.06.3.1.3). Also, the wide-field inhibitor of the FD1 cell has got a significantly more extended receptive field than the FD1 cell itself (Egelhaaf, M., 1985a; 1985b; Warzecha, A. K. *et al.*, 1993; Krapp, H. G. *et al.*, 2001). But most importantly, object motion has to be out of phase with background motion to efficiently activate the FD cells (Egelhaaf, M., 1985b), which is not a requirement for STMDs in hoverflies detecting small targets (see above). A neural circuit tuned to detect looming objects in locusts (Gabbiani, F. *et al.*, 2004, see Section 1.06.3.2.3.(ii)) needs to solve a similar problem. Its specificity to sense image expansion could be easily corrupted by self-motion-induced optic flow. In case of the locust, inhibitory feed-forward loops combined with a lateral inhibition network that acts on local-motion-sensitive inputs suppress responses to wide-field motion (e.g., Simmons, P. J. and Rind, F. C. 1992, see Section 1.06.3.2.3.(iii)).

1.06.3.2.3 Distance control and looming detection

Besides its role in estimating target size and controlling aerial chases (see Section 1.06.3.2.2), distance estimation plays an important role in a number of other visually guided outer-loop control tasks. We already mentioned its significance for avoiding collisions by integrating translation-induced optic flow in the blowfly where the underlying neural mechanism exploits directional wide-field motion (see Section 1.06.3.1.3.(ix)).

A special case of optic flow either due to an object approaching a stationary observer or due to an observer approaching a stationary object is image expansion. The key feature of image expansion is its inherent radial distribution of flow vectors all pointing outward from a singularity, which defines the approach direction. Image expansion is readily described by the translation term of the optic flow equation [1a], given a nonuniform distance distribution – which in natural environments always holds true. Let us assume an animal approaching a close-by object along a straight translation trajectory that sticks out from the background. In such case it will experience image expansion in two ways: (1) due to the animal's self-motion relative to the background an expansion pattern will be cast on its eyes (Figure 14(a)) and (2) because the object is closer to the animal than the background, the object will pop out of the optic flow pattern by generating local flow vectors of greater magnitude (Figure 14(b), red arrows). The other case, that is, the object is approaching a stationary observer, trivially results in only the object-included expansion pattern – since without self-motion no global optic flow is generated. Object-induced pattern expansion in either case is often referred to as looming stimulus. Looming stimuli contain sufficient visual information to estimate relative distance and to trigger a variety of behavioral responses in insects including landing in flies (e.g., Wagner, H., 1982), escape behavior in flies (e.g., Holmqvist, M. H. and Srinivasan, M. V., 1991), cockroaches (Camhi, J. M. and Levy, A., 1988), and locusts (Rind, F. C and Simmons, P. J., 1999; Gabbiani, F. *et al*, 2004), as well as controlling distance in the hovering hawkmoth (e.g., Farina, W. M. *et al.*, 1994). The potential role of pattern expansion for collision avoidance in freely flying *Drosophila* (Tammero, L. F. and Dickinson, M. H., 2002) we already mentioned in Section 1.06.3.1.3.(ix)

Here we will focus on hovering in hawkmoths and on the detection of looming objects in locusts to illustrate a couple of general principles in processing visual information used for outer-loop control. In both hawmoths and locusts, the activity of identified neural circuits and cells can be nicely linked to distinct and quantifiable behaviors. These animals are therefore ideal model systems to investigate task-specific neural computations – in case of the locust – down to the level of the underlying biophysical mechanisms.

1.06.3.2.3.(i) Distance control in hovering hawkmoths There are two well-studied systems in which the detection of change in distance between the animal and an object is investigated: landing and collision avoidance. Both behaviors require the detection of looming stimuli for the measurement of the change in distance and require information about object trajectory and velocity. Both result in a switch from one motor pattern, forward flight or sitting and feeding, to another, landing or avoidance behavior, respectively. The objective of the computation in both cases is to detect a change in distance and to find a threshold for the measured change to switch to a different motor pattern. In *Manduca sexta* (Sphingidae, Lepidoptera) we investigate a third behavioral paradigm that needs excellent detection and compensation for any change in distance, but here the context is distance control to a flower during feeding. *M. Sexta*, a hummingbird hawkmoth, flies rapidly, is highly maneuverable, and feeds while hovering in front of flowers. They have large superposition eyes, designed for optimal performance

under low-light conditions. The moths approach flowers fast, then decelerate several times, and finally stop precisely at a distance allowing them to insert the proboscis into the flower (Farina, W. M. *et al*., 1994). During this maneuver, the moths have to decide when to decelerate and to switch from forward flight to hovering. This can be viewed as a behavior analog to both landing and collision avoidance with respect to the requirements it poses for the visual system. But instead of landing on the blossom, the moths stay airborne and hover in front of the flower to reach the nectar with their long proboscis. To be able to successfully feed they have to maintain exact position in front of the flower even if it moves, irrespective of the direction of movement. The objective here is to detect the change in distance, monitor it, and maintain this fixed distance; this is in essence an optomotor control task and requires completely different mechanisms than landing or evasive maneuvers. The animal has to monitor both its approach and its retreat from the flower and has to compensate for the change to keep the distance stable. Time-to-collision networks like those proposed for the landing response or the escape response are concerned only with the approach of an object and are not designed to compute compensatory behavior. It is therefore interesting to investigate and to contrast the neuronal properties of these two different behavioral paradigms as the stimuli eliciting these behaviors are the same but the requirements for the execution of the appropriate motor patterns are quite different.

Looming stimuli can be detected in three principally different ways. The animal can detect the expansion/contraction flow field, the increase in object area, or the increase in object parameter or edge length. Wicklein M. and Strausfeld N. J. (2000) and Wicklein M. and Sejnowski T. J. (2001) designed and used a host of different stimuli with the goal to dissect these different detection mechanisms. They are using real, for example, expanding objects and simulated looming stimuli, e.g., rotating spirals and expanding/contracting bull's-eye patterns. These stimuli were designed to either provide stimulation to only one of the above mechanisms or have different temporal signatures for multiple mechanisms. Intracellular recordings in *M. sexta* identified two classes of wide-field spiking neurons that respond to looming or receding stimuli (Wicklein, M. and Strausfeld, N. J., 2000). These neurons do not habituate to repeated stimulation, which is in contrast to the LGMD but similar to fly optomotor neurons. The looming-sensitive neurons in the hawkmoth respond to both approach and retreat of an object and are able to distinguish between both. Two of the three above stated principally different mechanisms of looming detection are realized in the moth. Edge length detection (ELD) neurons, type 1 cells distinguish expansion from contraction on the base of changing perimeter length. These neurons are not sensitive to motion stimuli and respond only to stimuli in which the edge length of an object is increasing or decreasing. Flow field detection (FFD) neurons, type 2 cells, use motion cues to distinguish between expanding and contracting objects. Each FFD cell has a preferred and a null direction for both horizontal and vertical movement. So unlike the fly-motion-sensitive neurons the cells respond to both horizontal and vertical motion but distinguish for each motion orientation between a preferred and a null direction. Neurons with all four combinations of preferred directions, up-left, up-right, down-left, down right, have been found. Both ELD and FFDs neurons consist of two populations with opposing preferred directions for approach and retreat. One population responds with an increase in response strength to an expansion and a reduction of response strength when stimulated with a contracting stimulus; these cells are termed expansion cells. The other subset shows an increase in response strength when exposed to a contracting stimulus and shows a reduction in response strength when stimulated by an expanding stimulus. These cells are termed contraction cells. Both ELD and FFD neurons have front- to frontolateralal receptive fields and are wide-field neurons, with large up to 90° wide receptive fields. The two different cell classes also differ in their morphology and these differences can be used along side the physiological characterization of the neurons to identify a cell as ELD or FFD and set them apart from other neurons in the optic lobes that were already described in *M. sexta* (Milde, J. J., 1996; Rind, F. C. 1972). ELD neurons have arborizations in the innermost medulla layer, the outermost lobula layer, and throughout the lobula plate. They project to the posterior slope. FFD neurons have dense arborizations in the outermost layer of the medulla and in the ipsilateral or contralateral posterior slope; their cell bodies sit in a cluster between the calyces of the MBs.

Wicklein M. and Sejnowski. T. J. (2001) created a conceptual model for the ELD neurons and implemented this model in MATLAB taking the physiological and anatomical properties of the ELD neurons into account. As described above the input structure of the ELD neurons is divided between three neuropils, the medulla, the lobula, and the lobula plate. From anatomical studies we know that there has to be at least one

synapse between the outer medulla and the lobula or the lobula plate; this means that information that is present on the retina at the same time will arrive earlier at the medulla inputs, then at the inputs of the cell in the lobula and the lobula plate. This delay in input processing between different parts of the input arborizations in the ELD neuron is a main feature in the model and provides the model cell with the asymmetrical response characteristics seen in the recordings. To assess the validity of the model we tested both the model and the neurons with the same stimuli. The stimuli were presented to the input layer of the model, which projects to edge detectors whose output was summed spatially over the whole or parts of the input field, followed by a time derivative. The model behavior matched the neuronal behavior qualitatively well for a range of moving and looming stimuli.

Looming-sensitive neurons can be found throughout the animal kingdom including the nucleus rotundus of pigeons (Wang, Y. and Frost, B. J., 1992; Sun, H. and Frost, B. J., 1998), in the optic tectum of frogs (Arbib, M. A. and Liaw, J. S., 1995), and in area MSTd of primates (Duffy, C. J. and Wurtz, R. H., 1991; Tanaka, K. *et al.*, 1989). Recordings from single units in the primate MSTd have demonstrated neurons that discriminate between looming and antilooming, and between outward and inward spiral rotation (Graziano, M. S. *et al.*, 1994).

1.06.3.2.3.(ii) Detecting looming objects in locusts Like the fly in the context of directional motion vision, the locust is one of the most successful model systems in the context of looming detection. The reason for this is an impressive data body on the organization of its nervous system and many behavioral and electrophysiological studies on the control of movements in general (rev.: Burrows, M. 1996), and also in the context of various visuomotor control tasks (e.g., Reichert, H. and Rowell, C. H. F., 1986; Rowell, C. H. F., 1988; Eggers, A. *et al.*, 1991; Baader, A. *et al.*, 1992; Preiss, R., 1992; Robertson, R. M. and Reye, D. N., 1988; Spork, P. and Preiss, R., 1993; Santer, R. D. *et al.*, 2005; Santer, R. D. *et al.*, 2006).

An identified circuit consisting of the lobula gaint movement detector, LGMD, and its postsynaptic target neuron, the descending contralateral movement detector, DCMD, conveys information about approaching objects to the motor centers in the thoracic ganglia (Burrows, M. and Rowell, C. H. F., 1973). The response properties of the LGMD/DCMD have been extensively studied to address key issues of neuroscience including habituation, spike frequency adaptation, contrast- and shape-invariant neural responses, biophysical mechanisms underlying neural multiplication, and – more recently – the plasticity of visuomotor pathways (e.g., habituation: O'shea, M. and Rowell, C. H., 1975; Matheson, T. *et al.*, 2004; Gray, J. R., 2005; Guest, B. B. and Gray, J. R. 2006; spike frequency adaptation: Gabbiani, F. and Krapp, H. G., 2006; stimulus invariance: Simmons, P. J. and Rind, F. C., 1992; Gabbiani, F. *et al.*, 2001; neural multiplication: Hatsopoulos, N. *et al.*, 1995; Gabbiani, F. *et al.*, 1999; Gabbiani, F. *et al.*, 2002; plasticity: Rogers, S. M. *et al.*, 2007; rev.: Gabbiani, F. *et al.*, 2004).

The LGMD neuron has a conspicuous morphology (Figure 16(a)). It possesses three distinctly different dendritic input arborizations and a long axon along which action potentials are propagated toward its terminal ramifications in the lateral protocerebrum (Figures 16(a) and 16(b)). Each spike in the LGMD elicits, via a mixed chemical/electrical synapse exactly one spike in the postsynaptic DCMD (O'Shea, M. and Williams, J. L. 1974; Rind, F. C., 1984; Killmann, F. *et al.*, 1999). Attached to this faithful 1:1 transmission are two very useful properties of the circuit: Firstly, the LGMD can be easily identified even without intracellular staining as it is the only neuron that always generates a spike 1–2 ms before the DCMD fires a spike. Secondly, if only the spike frequency of the LGMD is of interest – as opposed to the neuron's intracellular membrane potential changes – this information is provided by extracellular DCMD recordings, easily kept stable for several hours.

As the LPTCs in the fly, the LGMD integrates thousands of local inputs. Its excitatory main dendrite spans the entire lobula and receives retinotopic input from local-motion-sensitive elements. Distal dendritic areas integrate signals obtained from the frontal visual field. The caudal visual field is mapped onto the proximal dendritic areas (O'Shea, M. and Williams, J. L. 1974). Two smaller dendritic fields receive nonretinotopic feed-forward inhibition – one activated by light-off and the other one by light-on stimuli, respectively (O'Shea, M. and Williams, J. L. 1974; Simmons, P. J. and Rind, F. C., 1992). A lateral inhibition network established between the arrays of local excitatory inputs is thought to be involved in local habituation to repetitive visual stimuli (O'shea, M. and Rowell, C. H., 1975). The integration properties of the LGMD proved to be highly sublinear and may play an important role in the neuron's invariant tuning to looming stimuli (Gabbiani, F. *et al.*, 2001; 2004;

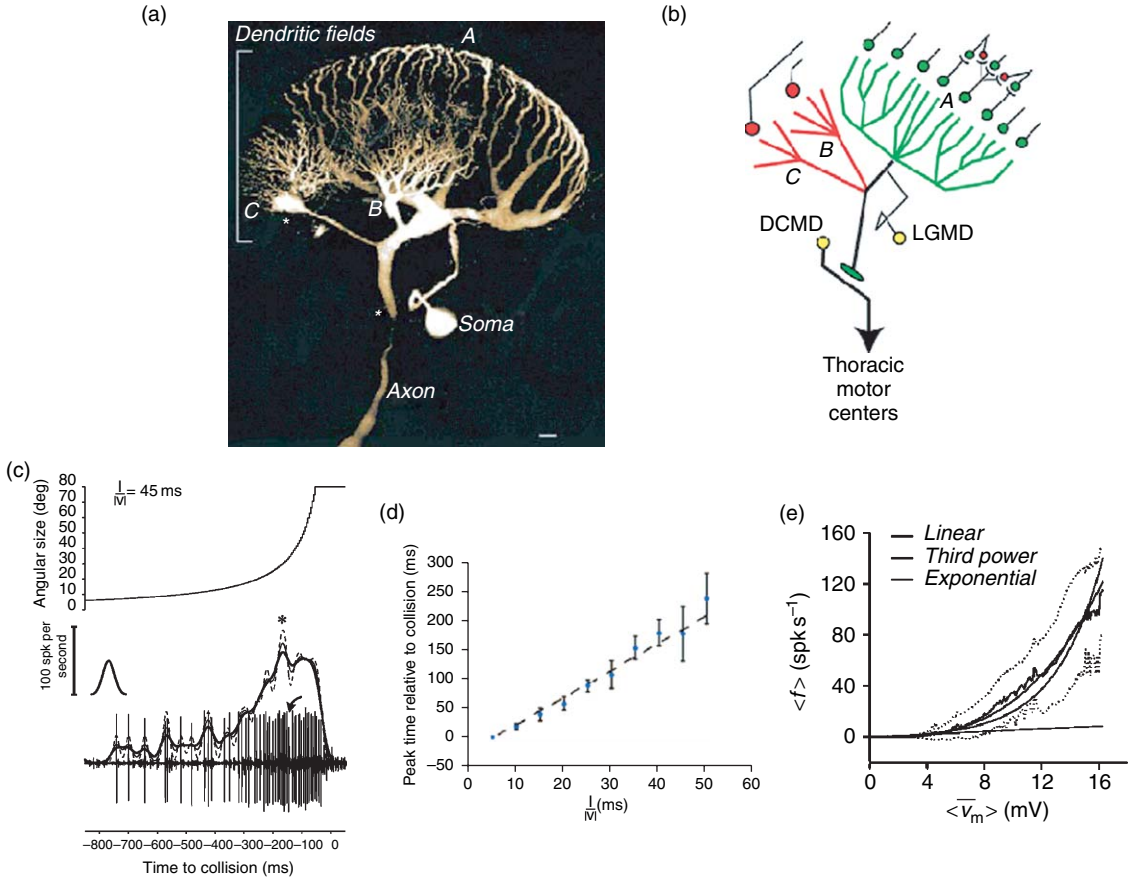

Figure 16 Detecting looming objects in the locust. (a) Two-photon confocal microscopic image of an lobula giant movement detector (LGMD) neuron in the locust. The neuron possesses three dendritic input arborizations, one excitatory (A) and two inhibitory fields (B and C), which receive retinotopic and nonretinotopic input, respectively. (b) Scheme of the LGMD and its target neuron, the descending contralateral movement detector (DCMD). (c) A looming stimulus (upper trace) induces an increase in LGMD/DCMD spiking activity that reaches a maximum close to the potential collision and then decays again. (d) The time of the peak activity is linearly related to the combined parameter l, absolute half-width of the stimulus, over v, the approach velocity of the looming object. This relationship suggests that the peak activity occurs at a certain time delay after the stimulus has exceeded a fixed angular threshold on the eye. (e) Relationship between spike rate and membrane potential changes in the LGMD neuron. The experimental data are best fitted with a third power law function, which is close to an exponential function. Such expansive nonlinear relationship was predicted by a model that describes the LGMD/DCMD responses over time as a function of retinal expansion velocity and retinal size of the looming object. For further explanation see text. Adapted from Gabbiani, F., Krapp, H.G., Koch, C. and Laurent, G. 2002. Multiplicative computation in a visual neuron sensitive to looming. Nature 420, 320–324; Gabbiani, F., Krapp, H.G. and Laurent, G. 1999. Computation of object approach by a wide-field, motion-sensitive neuron. J. Neurosci. 9, 1122–1141.

Krapp, H. G., and Gabbiani, F., 2005; Guest, B. B. and Gray, J. R., 2006).

Studies in the 1970s originally described the LGMD as an acridid movement detector responding briskly to any kind of motion presented in its extended receptive field (O'Shea, M. and Rowell, C. H., 1976; Rowell, C. H. and O'Shea, M., 1976; Rowell *et al.*, 1977). Further experiments revealed the neuron to respond particularly well to approaching objects, or looming stimuli (Schlotterer, G. R., 1977; Pinter, R. B. *et al.*, 1982). Objects directly approaching the eye did strongly activate the neuron independent of pattern contrast, while receding objects caused only weaker responses (Rind, F. C., 1990; Rind, F. C. and Simmons, P. J., 1992). Responses to wide-field motion were thought to be suppressed by mutual inhibition of separate pathways processing opposite contrast polarities (Simmons, P. J. and Rind, F. C., 1992). It was thought that the LGMD tracks object approaches by increasing its spike frequency as the looming object assumes an increasingly bigger angular size on the retina (Rind, F. C. and Simmons, P. J., 1992; Rind, F. C

and. Simmons, P. J., 1997). Based on a series of studies it was concluded that the LGMD neuron encodes the angular acceleration of an approaching object (e.g., rev.: Rind, F. C. and Simmons, P. J., 1999). A numerical model of the LGMD/DCMD circuit (Rind, F. C. and Bramwell, D. I., 1996) inspired the design of collision avoidance system implemented on a robot platform (Blanchard, M. *et al.*, 1999).

In the mid-1990s, the relationship between visual stimulus parameters and the neuron's response over time was studied more systematically. Hatsopoulos N. *et al.* (1995) realized that during a simulated object approach the LGMD activity reached a maximum and then steeply dropped – in most cases – while the stimulus was still expanding. The experimental data were fitted with a phenomenological model to describe the LGMD spike frequency in time. The model combined two visual parameters in a multiplicative way: the approaching object's change in angular size, $\mathrm{d}\theta/\mathrm{d}t$ and the instantaneous angular size, θ (Hatsopoulos, N. *et al.*, 1995). It predicted that for any given ratio between the absolute halfsize of an object, l, and the approach velocity, v, the neuron's peak response always occurs at a fixed time delay after the retinal projection of the object exceeds a certain angular threshold (ibid). Meanwhile, several studies by different groups working on the LGMD/DCMD circuit confirmed such relationship (Gabbiani, F. *et al.*, 1999; Gray, J. R. *et al.*, 2001; Matheson, T. *et al.*, 2004).

Such angular threshold computation or similar models involving a multiplication operation in the context of flight steering or escape behavior were also proposed for species including crabs (Schiff, W. 1965), pigeons (Sun, H. and Frost, B. J., 1998), frogs (Yamamoto, K. *et al.*, 2003), and fish (Preuss, T. *et al.*, 2006). This hints at a general principle in the detection of looming objects across phyla. Naturally, the question arises of how the proposed neural multiplication might be established in the nervous system? Even though the requirement of neural multiplication operations has been postulated for several sensory modalities – most notably in directional motion vision (see Section 1.06.3.1.2, rev.: Reichardt, W., 1987) and in auditory processing (Pena, J. L. and Konishi, M. 2001) – the underlying neural mechanisms are not yet completely understood (rev.: Gabbiani, F. *et al.*, 2004).

The model Hatsopoulos N. *et al.* (1995) put forward to describe the LGMD response over time, $r(t)$, is of the following form:

$$r(t) = \frac{\mathrm{d}\theta(t+\delta)}{\mathrm{d}t} \mathrm{e}^{(-\alpha\theta(t+\delta))} \qquad [4]$$

where $\mathrm{d}\theta(t+\delta)/\mathrm{d}t$ gives the expansion velocity of the approaching object at time t, plus the neural response delay δ, α is a coefficient, and $\theta(t+\delta)$ denotes the instantaneous angular size of the object at time $t+\delta$. The interpretation of the model is that during the early approach phase the expansion velocity term, $d\theta(t+\delta)/\mathrm{dt}$, dominates the LGMD spike frequency, which is, at later phases, strongly inhibited by the angular size term, $\theta(\mathrm{t}+\delta)$.

One way of performing a multiplication operation, used in analog very-large-scale integration (VLSI) circuits (Mead, C., 1989), is to take the logarithm of the input variables, sum them (eqn [5]), and backtransform the result by means of an exponentiation (eqn [6]).

$$\ln(r(t)) = \ln\left(\frac{\mathrm{d}\theta(t+\delta)}{\mathrm{d}t}\right) - \alpha\theta(t+\delta) \qquad [5]$$

With $a = \ln(\mathrm{d}\theta(t+\delta)/\mathrm{d}t)$ and $b = \alpha\theta(t+d)$ we may write:

$$r(t) = \mathrm{e}^{a-b} \qquad [6]$$

Assuming that, in a first approximation, the membrane potential of the LGMD corresponds to in a first approximation, to the sum of the integrated excitatory and inhibitory inputs, a–b, the required exponentiation could occur during the spike generation process (Gabbiani, F. *et al.*, 2002; 2004). Similar mechanisms have been proposed for simple and complex cells in cat primary visual cortex (Anderson, J. S. *et al.*, 2000) where the combination of synaptic noise and a linear threshold model results in an expansive nonlinearity when the neurons' membrane potential is transformed into a spike frequency (Carandini, M. and Ferster, D., 2000).

Recent experimental evidence suggests that the LGMD membrane potential is indeed transformed into a spike rate according to a third-order power law that comes close to an exponential function (Figure 16(e), Gabbiani, F. *et al.*, 2002). This finding is in agreement with the model proposed by Hatsopoulos N. *et al.* (1995).

Still, the question remains whether the inputs to the LGMD encode angular expansion velocity in logarithmic space and angular size in linear space, as eqn [5] implies. It has to be said that encoding velocity independent of size and encoding size independent of velocity is by no means a simple task in neural processing.

As far as the velocity-dependent excitatory inputs are concerned there is ample evidence for

logarithmic compression of the dynamic input range in the visual system (Laughlin, S. B., 1987). This includes the output of EMDs being logarithmically encoded in the velocity domain (Zanker, J. M. *et al.*, 1999). Together with a dendritic gain control mechanism as proposed for the fly LPTCs (Borst, A. *et al.*, 1995, see Section 1.06.3.1.3.(viii)), a size-independent logarithmic encoding of velocity might as well be a possible option for the LGMD. Furthermore, there is experimental evidence that the responses of local motion-sensitive elements presynaptic to the excitatory dendritic tree are indeed velocity-dependent (Krapp, H. G., and Gabbiani, F., 2005).

Regarding the size-dependent inhibitory input to the LGMD, so far, there is only indirect experimental evidence available (Gabbiani, F. *et al.*, 2005). If the forward inhibition is abolished using GABA antagonists, the peak firing rate of the LGMD neuron is delayed to occur closer to collision or even afterwards (Gabbiani, F. *et al.*, 2002). This result is compatible with the interpretation of the model: At later times during the approach, feed-forward inhibition, $-\alpha\theta(t+\delta)$ in eqn [5], dominates over the excitatory inputs, $\ln(\mathrm{d}\theta(t+\delta)/\mathrm{d}t)$, causing the firing rate to decrease and thus defines the timing of the LGMD peak response.

From a functional point of view the response properties of the LGMD neuron show some remarkable task-specific features which support its role in detecting approaching objects. The LGMD does not respond particularly well to optic flow as generated during self-motion (Simmons, P. J. and Rind, F. C., 1992). The lateral inhibition network acting on the excitatory input elements was suggested to prevent synaptic fatigue (O'Shea, M. and Rowell, C. H., 1976). Spike frequency adaptation shapes the activity pattern in the LGMD and may also prevent the LGMD output range from saturating (Gabbiani, F. and Krapp, H. G., 2006). The physiological process underlying this adaptation, that is, opening of calcium-dependent potassium channels, is readily explained by a model originally proposed for vertebrate neurons (Wang, X. J., 1998). Furthermore, the LGMD receptive field spans almost an entire visual hemisphere (Krapp, H. G. and Gabbiani, F., 2005) with an isotropic sensitivity profile to looming objects independent of the approach direction (Gabbiani, F. *et al.*, 2001; Rogers, S. M. *et al.*, 2004). Though such an extended receptive field does allow the animal only to detect whether an approach occurs from in front, left, or right it is sufficient to initiate adequate behavioral action. Correspondingly, behavioral experiments in freely moving locusts confronted with looming stimuli from different directions did not show a correlated relationship between approach direction and the direction of the escape jumps. The locusts' jumps were only away from, but not in a certain angular relationship relative to the direction of object approach (Santer, R. D. *et al.*, 2005). Open-loop experiments in tethered flying locusts suggest that in response to looming stimuli, different flight maneuvers, i.e., the initiation of evasive steering or gliding, depend on the level of spiking in the DCMD (Santer, R. D. *et al.*, 2006).

Recent studies on the LGMD/DCMD circuit in locusts addressed the question of how differences in behavioral states are related to differences in neural processing. In *Schistocerca gregaria*, a locust species that comes in two phases – one solitarious and one gregarious – the LGMD habituates to repeated stimuli in a phase-dependent way: In gregarious animals, which fly during daytime, and in swarms the LGMD habituates only mildly while in solitarious, which generally avoid conspecifics and fly during the night, the LGMD activity strongly habituates (Matheson, T. *et al.*, 2004). Another difference between the two phases is an overall lower spiking activity in solitarious animals. This difference was found to be compensated for by increasing the gain of an identified synapse between the DCMD and one of its target motor neurons that controls the activity in a leg muscle involved in the execution of escape jumps (Rogers, S. M *et al.*, 2007). The transition from behaviorally solitarious to gregarious locusts, which is usually caused by overpopulating a given area, partly occurs within several hours. This suggests that the differences between the functional properties of the LGMD/DCMD circuit in the two phases require intermediate-term neural plasticity.

Looming detection in locusts is an area where much progress has been made over the last couple of years. Not only in the sense that we now better understand the neural basis of specific visually guided behaviors in insects but also because several studies addressed questions of fundamental interest to neuroscience across species. One such principal question is: how do neurons multiply? Promising ideas have been put forward (Hatsopoulos, N. *et al.*, 1995), which were supported by experimental evidence (Gabbiani, F. *et al.*, 2002; rev.: Gabbiani, F. *et al.*, 2004). The key to further our understanding of the underlying biophysical mechanisms,

however, requires an approach that combines *in vivo* electrophysiology, compartmental modeling, and quantitative behavioral studies. A detailed compartmental model of the LGMD to investigate the neuron's passive integration properties has been recently presented (Peron, S. P. *et al.*, 2007) and awaits its extension to include active membrane properties. However, there is a lack of naturalistic stimulus sequences that capture the actual visual input a locust experiences in the wild, either during free flight or while sitting on the ground when an object approaches. Naturalistic stimulus sequences could be mapped onto the inputs of the compartmental model and/or may be used for stimulation during electrophysiological experiments to learn more about the LGMD's integration properties. Such replay experiments certainly do not solve all remaining problems but they might result in some new insights as they did in the research on directional motion vision of the fly (see Section 1.06.3.1.3.(ix)). It is important to keep in mind, however, that the results obtained from such replay experiments do not necessarily reflect the system's closed-loop behavior. Sensory mechanisms of other modalities not activated during such open-loop experiments may be required to gate or modify the responses of the LGMD.

In a recent study on freely moving locusts, not only escape jumps in response to looming stimuli but also the muscle activity during distinctly different preparatory phases immediately before the animals' takeoff were video monitored (Fotowat, H. and Gabbiani, F., in press). A correlation analysis of the behavioral and muscle recording data in combination with separate DCMD recordings produced the following results: the different preparatory phases before jumping always occur at a certain time before the impending collision. The starting point of most of the preparatory phases could be related to the different levels of DCMD spiking, which did consistently reflect the looming stimulus to exceed consecutive angular thresholds on the animal's retina. The fact that, during the entire sequence, the timing of reaching consecutive activity levels was independent of the kinematic parameter, $1/V$, is consistent with the model proposed (eqn [4]).

The experiments in freely walking animals (Santer, R. D. *et al.*, 2005; Gabbiani, F. personal communication) present an elegant approach to get around the problem of working on restrained animals. The situation for the animals is almost natural – except for the lack of realistic short-range air pressure changes, which an approaching predator would probably produce and which cockroaches also exploit for triggering their escape behavior (Camhi, J. M., 1993). The next step would ideally be to record neural and muscle activity in freely flying animals – either in combination with their immediate visual input using micro cameras or when the animals' trajectories and head movements are observed to reconstruct the visual input. Locusts, as apposed to flies, are big enough to handle a decent payload and indeed did carry amplifier and telemetric transmission gear for muscle recordings already in the mid-1990s (Fischer, H. *et al.*, 1996). It is probably just a matter of time until miniaturization of integrated electronic circuits, including micro cameras, will allow for neural recordings during flight.

1.06.3.3 Image Segmentation – The Detection of Orientated Contours

The segmentation of images is commonly associated with the ability to discriminate between contours of different orientation. Early work in mammals suggested simple and complex cells in areas V17, 18, and 19 to be involved (e.g., Hubel, D. H. and Wiesel, T. N., 1959). These cells are arranged in cortical columns and hypercolumns the proper development of which requires early visual experience (Hubel, D. H. and Wiesel, T. N. 1965).

Anatomical studies in insects have shown experience-dependent plasticity at different levels of the visual system (e.g., Barth, M., *et al.*, 1997, see Section 1.06.3.1.3.(v)). Besides ontogenetic plasticity during the development, insects perform remarkably well in learning tasks also, which require them to distinguish between visual cues such as object shape and size, edge and pattern orientation, as well as color (see Section 1.06.4.1). The classic experimental model system is the honeybee in which a remarkable data body on learning and memory based on visual cues has been accumulated since the work of von Frisch K. (1965) (rev.: Wehner, R., 1981; Srinivasan, M. V., 1994). The reason for honeybees to be different was partly attributed to the fact that these animals live in social aggregates. Honeybees are required to memorize the location. First, because they need to be able to find the food source again for themselves after they have returned to the hive. Second, they are required to communicate the yield and location of the food sources to their hive mates by means of the famous waggle dance (Esch, H. E. *et al.*, 2001).

Meanwhile, it becomes evident, however, that other insects not living in social aggregates and presumably lacking intraspecific communication also show the capability of learning and memory (see Section 1.06.7). Learning and memorizing is the second step following the identification of a relevant object in a particular context, for instance, feeding and requires the segmentation of the retinal input.

Behavioral studies recently showed that blowflies too are capable of distinguishing between differently oriented gratings and of memorizing those patterns that were rewarded during training sessions. Gratings tested against each other in these experiments were differently oriented by 90°, that is, horizontal versus vertical orientation, or oblique patterns tilted by 45° to the left versus right (Campbell, H. R., 2001; Campbell, H. R. and Strausfeld, N. J., 2001). The animals were even able to distinguish between orientation differences as small as 5° when they challenged with vertically and nearly vertically oriented patterns (Campbell, H. R. and Strausfeld, N. J., 2001).

Campbell H. R. and Strausfeld N. J. (2001) discussed several potential mechanisms, which may underlie the fly's orientation discrimination ability. Retinotopic template matching, suggested by earlier studies to be involved in distinguishing between different patterns in *Drosophila* learning experiments (Dill, M. *et al.*, 1993; Dill, M. and Heisenberg, M., 1995), was not required to accomplish the orientation discrimination task (Campbell, H. R., 2001). Although several parallel mechanisms based on directional motion cues could not be excluded for sure, a dedicated orientation-selective pathway was assumed that was inspired by a model on earlier pattern discrimination experiments in honeybees (Srinivasan, M. V., 1994; Chandra, B. C. S. *et al.*, 1998). The idea was that three orientation-selective channels at an angular spacing of 120° with a half-width orientation tuning of about 90° could account for the observed behavioral data (Campbell, H. R. and Strausfeld, N. J., 2001).

The neural correlate underlying orientation selectivity in insects is not very well-known. Some electrophysiological studies in honeybees (e.g., Yang, E.-C. and Maddess, T., 1997), dragonflies (O'Carroll, D.C., 1993), and earlier work in flies (McCann, G. D. and Dill, J. C., 1969) showed that insect nervous systems are endowed with orientation-selective neurons. However, a detailed description of the morphology and electrophysiological response properties of orientation-selective neurons was still missing.

Detailed anatomical studies (Strausfeld, N. J. and Okamura, J. Y., 2007) in connection with preliminary electrophysiological results (Okamura, J. Y. and Stausfeld, N. J., 2007) suggest that the optic glomeruli in the lateral protocerebrum of the fly are involved in the discrimination between differently oriented contours. The interconnectivity between individual optic glomeruli is somewhat reminiscent of the interconnectivity found among glomeruli of the antennal lobes processing olfactory and mechanosensory information. The optic glomeruli receive two sorts of inputs: (1) They receive input from columnar lobula complex neurons directed to specific glomeruli. The terminals of these neurons do not always directly contact any descending neurons but may connect to local interneurons, which set up an intrinsic network within each of the glomeruli. (2) The second type of inputs is provided by a class of wide-field neurons collecting information from both the lobula and the medulla (Strausfeld, N. J. and Okamura, J. Y., 2007).

Individual intracellular recordings from identified neurons connected to the glomeruli circuits seem to suggest these anatomical structures to be involved in the distinction between different contour orientations. Some neurons encountered had restricted dendritic fields in the lobula as well as in the lobula plate and, correspondingly, had small receptive fields. Together, these neurons build a population that covers the entire monocular visual field. Their response properties were somewhat heterogeneous, some responding in a directional-selective, some in an orientation-selective way or both. Four distinctly different morphological types were found. Individual specimens of each of the three classes were broadly tuned to specific orientations. Relay neurons in between the glomeruli and one local interneuron, instead, had a narrower orientation tuning (Okamura, J. Y. and Strausfeld, N. J., 2007).

The electrophysiological data presented in the latter study mark a first step and in combination with the solid anatomical data give a strong hint at which area in the insect brain might be dealing with pattern segmentation. A greater database obtained from repeated and systematic electrophysiological characterizations of the different cell types would be needed to obtain a conceptual model of how orientation-selectivity is actually established in the fly nervous system. Finally, the transfer function between the outputs of the optic glomeruli, which carry information relevant to outer-loop control, and

the neurons involved in maintaining postural stability needs to be determined.

1.06.4 Exploiting Electromagnetic Properties of Light

So far the visual mechanisms that we discussed, such as motion vision or detection of small objects, are coping with the detection of light intensity changes. The reason for this is that most of the reviewed mechanisms so far are driven by monochromatic contrast. In the next two sections we will investigate how invertebrates analyze and utilize properties arising from the electromagnetic nature of light: its spectral content and e-vector orientation. Color is intrinsic to light whereas polarization, patterns of e-vector orientation, arise only through scattering and reflection of light.

Visible light comprises just a part of the electromagnetic spectrum. The wavelengths that animals can detect are between 300 and 800 nm, while the far-infrared spectrum between 700 and 800 nm is visible only to few species. Most invertebrate trichromates possess a UV receptor, maximally sensitive to wavelengths around 350 nm, a blue receptor with maximal sensitivity around 450–480 nm, and a green receptor with maximal sensitivity around 500–550 nm (Kelber, A., 2006).

Polarized light arises from scattering of sunlight within the atmosphere and the hydrosphere and from reflection of light by shiny surfaces, such as water, leaves, scales, and cuticle (Horvath, G. and Varju, D., 2004). In contrast to color, polarized light has an intrinsic spatial component, the angle of polarization or e-vector orientation. This feature is exploited by invertebrates for navigational purposes (Wehner, R. and Labhart, T., 2006), as discussed in Polarization Vision. But first we will discuss the detection and the use of the chromatic information of light.

1.06.4.1 Processing of Color Information

A wide range of species in the animal kingdom and a host of invertebrates possess multiple types of photoreceptors and color vision (see tables 1 and 2 in Kelber, A. *et al.*, 2003). This is remarkable considering that an animal investing into color vision will have lowered absolute sensitivity and in many cases also lowered spatial resolution. Additionally the cost of neuronal processing and analysis of spectral information should act as an energetic constraint on the number of spectral receptor types (Laughlin, S. B., 2001). So the question arises: Why is color vision an evolutionary useful trait despite these obvious costs? Hence, why do so many animals possess color vision?

It is rather easy to convince oneself of the necessity of motion vision for any mobile animal, as it is clearly necessary to monitor ones motion in space, to steer a course, and to avoid collisions (see Sections 1.06.3.1 and 1.06.3.2). It is a bit harder to define a behavior that would be impossible to achieve without chromatic information and in which color vision is truly indispensable.

1.06.4.1.1 Reasons for color vision

One argument for color vision is that chromatic information is used for object detection and identification because the chromatic signature of objects should be more reliable for identification. The reason for this is that the spectral composition of the illumination varies less than the intensity (Kelber, A., 2006).

Campenhausen C. V. (1986) and Maximov V. V. (2000) argue that color vision evolved to filter out the large intensity differences between sunlit and shady spots and the flicker that they generate. The usefulness of knowing the color of light could have been an additional reason for color vision to evolve. One example for this is the detection of the solar and antisolar halves of the sky, which differ in the content of long-wavelength light. The identification of the solar half of the sky is useful for navigational purposes (see Section 1.06.4.2).

1.06.4.1.2 In what behavioral contexts is color vision used?

Bees, wasps, and butterflies foraging in a flower meadow would be one well-known example for a behavior that is undoubtedly mediated largely by color vision (Chittka, L. *et al.*, 1993). But other behaviors, both spontaneous and learned, such as mate recognition (Lepidoptera: Kelber, A., 1999a), camouflage (Lepidoptera: Starnecker, G., 1996), finding the correct food plant for oviposition (Lepidoptera: Kelber, A., 1999a), and nest finding (spiders: Peckham, G. W. and Peckham, E. G., 1894, hymenoptera: Steinmann, E. and Menzel, R., 1990) to name just a few, are also mediated at least in part by color vision (rev.: Kelber, A., 2006).

1.06.4.1.3 Visual pigments, photoreceptors, and filters

The relative likelihood of absorption of a photon defines the spectral sensitivity of a photoreceptor.

Once a photon is absorbed the electrical response of the photoreceptor is independent of the wavelength of the photon, which is called the principle of univariance (Rushton, W. A., 1965). This means that individual photoreceptors are color blind because the intensity of two visible spectra can always be adjusted to give equal receptor responses. Simply put, a green photoreceptor can be equally excited by a weak, low-intensity green light and a very intense blue light.

Visual pigments are G-protein-coupled receptors, which are composed of an opsin and a chromophore. The chromophore isomerizes when it absorbs a photon and this causes a confirmation change and activates phototransduction (Aidley, D. J., 1998). The chromophore and the opsin together specify the spectral sensitivity of the visual pigment. Retinal is the most common chromophore in the animal kingdom, but most insects use 3-hydroxyretinal. Usually a single photoreceptor cell contains one visual pigment, but there are exceptions to this rule. The swallowtail, for example, coexpresses two opsin genes in some of its photoreceptors (Kitamoto, J. *et al.*, 1998).

In invertebrates, the number of receptor types that are expressed is quite variable, ranging from a single spectral type in cephalopod molluscs (Messenger, J. B. 1981) to up to 16 different receptor types in stomatopod crustaceans (Cronin, T. W. and Marshall, N. J., 1989; Marshall, N. J., and Oberwinkler, J., 1999). Some spiders and crustaceans have two receptor types, but Salticidae (jumping spiders) may have four (Walla, P. *et al.*, 1996). Among insects, cockroaches and some ants have two receptor types, most bees and wasps have three, dragonflies and sawflies have four, and some flies and butterflies have five or more (rev.: Briscoe, A. and Chittka, L., 2001). In addition to the different spectral receptor types the sensitivity of photoreceptors can be changed in several ways by: (1) screening and sensitizing pigments; (2) diverse types of intraocular filters, cornea filters, and the filtering properties of distal receptor cells in tiered retinae; and (3) lateral filtering in single light-guiding rhabdoms in which several spectral receptors compete for photons (rev.: Kelber, A., 2006).

1.06.4.1.4 Receptor arrangement in the retina

The arrangement of photoreceptors in the eye has been studied intensely. In crustaceans and insects several different types of receptors can be found in a single ommatidium. Different receptor types can build a regular pattern in the retina or they can be randomly arranged. Examples for insects with randomly arranged retinae are *Papilio xuthus* (Arikawa, K. and Stavenga, D. 1997), the bumble bee (Späthe, J. and Briscoe, A. D., 2005), and the honeybee (Wakakuwa, M. *et al.*, 2005). As yet we do not understand what impact these different arrangements have on the neuronal coding of color vision.

Many animals have regionalized retinae where only parts of the eye are color-sensitive while other parts serve other functions like, for example, the polarization-sensitive dorsal rim area (DRA) in ants and locusts (see Section 1.06.4.2). In other species like some spiders and Stomadopods, only a small region of their visual fields is dedicated to sense color. In stomatopod eyes the color-sensitive area consists of only four rows of horizontal ommatidia (Marshall, N. J., 1988). Whereas in jumping spiders only the two principal eyes are color-sensitive and thus only a small area of their visual field can be analyzed for chromatic information (Land, M. F., 1985).

1.06.4.1.5 Color perception

In human vision, color has three distinct qualities, hue, saturation, and brightness. Hue and saturation are chromatic aspects of color. Brightness is the achromatic aspect of color; intensity-related cues are referred to as achromatic cues and the signal is an achromatic signal. Brightness describes how light or dark a stimulus is. Saturation describes how similar the color is to gray or white. A low saturation means the color is relatively close to gray or white, whereas a highly saturated color will be far removed from gray or white. Hue refers to color differences other than saturation and brightness and is described in terms of red, green, blue, etc. Hue and saturation are mediated by opponent mechanisms that involve the comparison of receptor outputs, while brightness involves only additive interactions.

1.06.4.1.6 When does an animal have color vision?

This is not a trivial question, because just the fact that an animal is in possession of multiple receptor types does not necessarily mean it is employing color vision. Each of the different receptor types could be used individually to drive a specific behavior. These behaviors would still be color blind and the corresponding channel would be an achromatic channel. In the honeybee, for example, single receptors are used for specific behavioral tasks and each of these channels is achromatic. In the bee, motion vision and high-resolution vision are based on the green receptor signal (Lehrer, M., 1994), polarization vision is based on the UV receptor

(Wehner, R., 1987), and all receptor types are pooled for phototaxis (Menzel, R., 1979). If more than one receptor type is used for a specific behavior and a ratio or difference of these receptor signals is computed this behavior is no longer color blind. In other words, if an animal possesses at least two spectrally distinct visual pigments in two different photoreceptors and compares their outputs, the result of this comparison, color opponency, is color sensitivity and will be largely independent of intensity. Therefore only if an animal can discriminate two lights of different spectral composition regardless of their relative intensity it is considered to employ color vision (Menzel, R., 1979; Neumeyer, C., 1991; DeValois, R. L. and DeValois, K. D., 1997).

1.06.4.1.7 Classifications of color vision

Color vision is classified as dichromatic, trichromatic, etc. depending on the number of lights required to match any spectral light. The number of colors that are needed to match any light cannot exceed the number of different spectral photoreceptors. But quite often it is lower than that, for example, humans do not use rods for color vision. For a trichromat, humans or bees, the intensities of the three primary spectra can match any light. Therefore in the case of trichromats, color can be specified by either the intensities of three known spectra required for a match or by the quantum catches of the three receptor types. A color can then be represented geometrically as a point in a color space whose dimensionality is given by the number of receptor types involved (3 for trichromats), which during color matching can be added positively or negatively. For a more detailed account of different color spaces see Kelber A. *et al.* (2003).

1.06.4.1.8 Behavioral tests for color vision

Lubock J. (1888) established that *Daphnia* sp. is color-sensitive and this was the first time that color vision was proven for an invertebrate. He tested *Daphnia*, which are positively phototactic, and found that they preferred light that was filtered with a yellow filter over the unfiltered light source. As the unfiltered light was higher in intensity at all wavelengths, he concluded that *Daphnia* has color vision preferring yellow over white light. Twenty-six years later, in 1914, von Frisch K. (1914) used associative learning with a food reward in the context of foraging to successfully demonstrate the use of achromatic and chromatic signals in honeybees. von Frisch's famous gray card experiment established irrevocably that bee's possess color vision. In that experiment the bees were trained to find and associate a food reward with a specific color. In the test that followed they had to choose between that color and many shades of gray. At least one of the gray shades should have been sufficiently similar in its achromatic signal to the trained color. If the bee discriminates the trained color successfully from all the gray shades, she must use color vision to complete the task, as she is not relying on achromatic cues. A huge body of data on bee color vision based on behavioral experiments is available (e.g., Kühn, A., 1927; von Helversen, O., 1972; Backhaus, W., 1991; Giurfa, M., *et al.*, 1995; Dyer, A. G. and Neumeyer, C., 2005; Wicklein, M. and Lotto, R. B. 2005; Späthe, J. *et al.*, 2006). A growing range of invertebrates were shown to have color vision when tested in different behavioral contexts and with different testing paradigms. One of the most astonishing results comes from night-flying hawkmoths who forage under starlight scotopic conditions under which humans are completely color blind. The moths use chromatic cues to find their flowers of choice (Kelber, A. *et al.*, 2002). Chapter Color in Invertebrate Vision gives a more detailed account of color vision under special conditions like low light levels. For a detailed list of invertebrates that were shown to have color vision see Kelber A. *et al.* (2003).

1.06.4.1.9 Neural mechanisms for color coding

Spectral opponency is the neural mechanism that has been found to code for hue contrast in primates and is also observed in invertebrates. Single receptors are detecting only quanta of light and cannot discriminate properties of light like its wavelength. They are color blind. Therefore output signals of multiple receptors that are tuned to different parts of the spectrum but observe the same visual area must be compared to get access to the spectral content. The same principle holds for the detection of polarization (see Section 1.06.4.2). Cells that compute such a comparison of different receptor outputs are called color-opponent neurons. Swihart C. A. (1971) was the first who found spectral-opponent neurons in insects. He recorded spectral-opponent neurons in the optic lobes and the protocerebrum of butterflies. Spectral opponency was also established in several other insect species including the locust (Osorio, D., 1986), the cockroach (Mote, M. I. and Rubin, L. J., 1981), and the honeybee (Kien, J. and Menzel, R., 1977a; 1977b; Hertel, H., 1980; Riehle, A. 1981; Hertel, H., *et al.*, 1987; Hertel, H. and Maronde, U.,

1987a; 1987b; Yang, E.-C. *et. al.*, 2004). In trichromates the three spectral inputs that arise from the photoreceptors in the retina are named according to their wavelength specificity as long – L, medium – M, and short – S wavelength receptors (Figure 17(b)). All spectral-opponent neurons recorded so far are characterized in principle by excitatory + and inhibitory − response patterns of the following kind: S + M − L−, S − M + L+, S + M − L+, or S − M + L− and the reverse combinations of these.

In insects and crustaceans, two anatomical types of photoreceptors are found, short or long visual fibers, which either terminate in the lamina, short visual fibers, or in the medulla, long visual fibers (see Section 1.06.2). In flies the long visual fibers constitute the chromatic pathway whereas the short visual fibers supply the achromatic motion-sensitive pathway. These two pathways are separated throughout the entire visual system (Strausfeld, N. J. and Lee, J. K., 1991). But flies seem to be an exception with this arrangement; in most insects and crustaceans both the short and long visual fibers contribute to the color pathway. For more details on different species see Kelber A. (2006).

The honeybee is the most thoroughly investigated invertebrate species for color vision and we will therefore use the honeybee to illustrate the principles of neuronal color coding (Figure 17(a)). Already at the first level of synaptic interaction in the lamina, separate pathways for achromatic contrast and spectral coding are formed. Four types of large monopolar cells (LMC) each with different input characteristics have been found. The first LMC is hyperpolarized by M and L receptor inputs and depolarized by the S receptor input. The second type of LMC is dominated by M receptor inputs and receives only weak L and S receptor inputs. The third LMC type receives only L receptor input. The forth and the last LMC type sums the inputs from all three receptor inputs and could represent a highly sensitive achromatic system (Menzel, R., 1974; Hertel, H. and Maronde, U., 1987a; 1987b). The outputs of all these LMCs are combined in the medulla with those of the S receptors that have long axons (long visual fibers) and project all the way to the medulla. Neurons recorded in the proximal medulla show spectral opponency similar to cells in the lobula and the protocerebrum. Two forms of opponency are found: (1) Tonic opponency, which seems to be the dominant form and can be found throughout the medulla, lobula, and the protocerebrum (Kien, J. and Menzel, R., 1977b; Hertel, H., 1980; Riehle, A., 1981; Hertel, H., *et al.*, 1987; Hertel, H., and Maronde, U., 1987b; Yang, E.-C. *et al.*, 2004). The neurons are excited or inhibited by a flash of monochromatic light in their sustained response. All combinations of L, M, and S receptor opponency possible as well as cells computing simple summations of two or all three receptor inputs have been recorded (Kien, J. and Menzel, R., 1977a; 1977b; Yang, E.-C. *et al.*, 2004). Interestingly the cells differ widely in their specific response patterns as well as in their receptive field size and structure. (2) ON/OFF or phasic opponency; this is observed much less frequently and seems to be present only in local neurons of the medulla. There two response patterns were found: S-OFF, M-ON, L-OFF, or S-ON and OFF, L-OFF (Hertel, H., 1980). The receptive fields of spectral-opponent neurons range from small, simple fields to large, complex receptive fields that can even

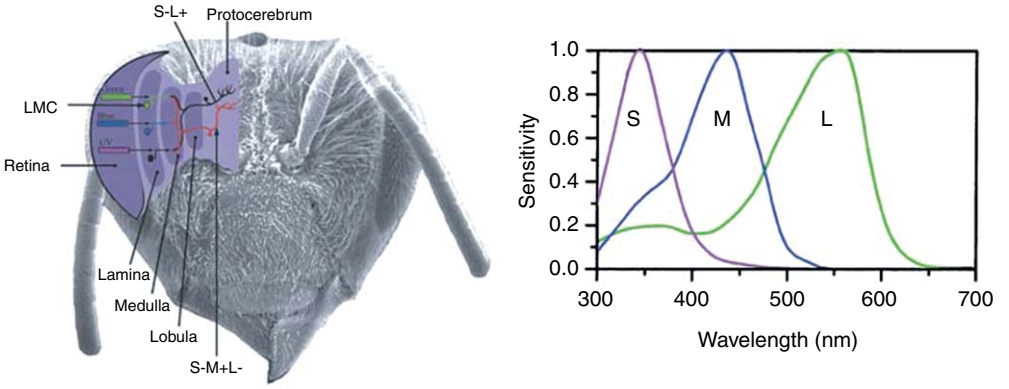

Figure 17 Color vision. (a) Scanning electron micrograph of a bee head. The inset shows a schematic depiction of the neuronal circuits involved in color vision. (b) Tuning curves of the S, M, and L receptors in the bee. Adapted from Chittka, L. and Raine, N. I. 2006. Recognition of flowers by pollinators. Curr. Opin. Plant Biol. 9, 428–435.

cover both eyes. But no center-surround spatial-opponent neurons like those observed in the vertebrate cortex have been found in the honeybee or any other invertebrate species so far. Spectral opponency neurons project mainly through two tracts: (1) the posterior optic commissure (POC), which runs between the left the and right visual hemisphere, and (2) the anterior optic commissure (AOC), which projects in a nonretinotopic manner to the MBs and the lateral protocerebrum (Hertel, H. and Maronde, U., 1987a; 1987b; Hertel, H. *et al.*, 1987; Ehmer, B. and Gronenberg, W., 2002). Anatomical data from Ehmer B. and Gronenberg W. (2002) were discussed in more detail in Section 1.06.2.

1.06.4.2 Polarization Vision

The ability to sense the polarization pattern of the sky and to make use of it for navigation is a trait shared by birds, fish, cephalopods, and arthropods (Horvath, G. and Varju, D., 2004). Polarization vision provides them with a powerful tool for a variety of orientation and navigation tasks or simply allows them to detect bodies of water in the case of some water-seeking insects (Schwind, R., 1984; 1991; Horvath, G. and Zeil, J., 1996; Kirska, G. *et al.*, 1998; Wildermuth, H. 1998). Many insects are able to use polarization vision for course control (flies: Wolf, R. and Heisenberg, M. 1980; von Philipsborn, A. and Labhart, T. 1990), as a global reference cue for the compass system in migratory species such as locusts (Mappes, M. and Homburg, U., 2004), and for foraging and homing in bees, ants, and fiddler crabs (Wehner, R., 1984; 1994; 1997; Zeil, J. and Layne, J. E., 2002; Wehner, R., and Srinivasan, M. V., 2003).

1.06.4.2.1 Properties of polarized light

Light can get polarized by scattering in air or water or when it reflects from surfaces. The polarization patterns created are different in each case and can be used to aid different behaviors (rev.: Wehner, R. and Labhart, T., 2006), e.g., light reflected from the surface of water bodies attracts water-seeking insects (Schwind, R., 1984). In this account we will concentrate on the situation created when light is scattered in air and its use for navigation. Here polarization vision is based on the detection of the polarization pattern that consists of concentrically arranged e-vectors around the sun that span the entire sky. These patterns vary systematically across the sky and depend on the sun's position. They are caused by the atmospheric scattering of sunlight. This scattering results in the partial plane polarization of sunlight. The prevailing oscillation plane e-vector is oriented orthogonal to an imaginary straight line between an observed point in the sky and the position of the sun (Figure 18(a)).

1.06.4.2.2 Adaptations to e-vector detection in the eye

von Frisch K. (1967) showed that only very small patches of sky of 10–15° wide are needed for insects to detect and orient toward polarization patterns.

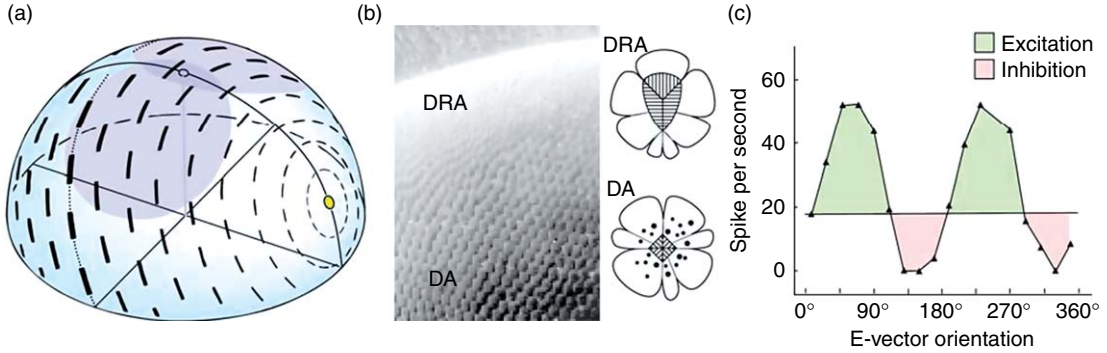

Figure 18 Polarization vision. (a) A representation of the polarization pattern observed at a sun elevation of 24°. The e-vector orientations are depicted as bars, their length and width indicate the degree of polarization. The shading represents the size and the location of the visual fields of polarization-sensitive interneurons (POL1 neurons) of the crickets. (b) Ommatidia in the specialized dorsal rim area (DRA) region of the field cricket are compared with regular ommatidia in the adjacent dorsal area (DA). Left: Scanning electron micrograph showing strongly reduced faceting in the DRA cornea. Right: Schematic representations of cross sections through ommatidia from both the DRA and the DA. (c) Polarization opponent response of a field cricket POL neuron. A strong modulation of spike frequency can be observed despite a low degree of polarization of 19%. Excitation is shown in green shading and inhibition in red shading. Adapted from Labhart, T. and Meyer, E. P. 2002. Neural mechanisms in insect navigation: polarization compass and odometer. Curr. Opin. Neurobiol. 12, 707–714.

Similarly new studies (Henze, M. J. and Labhart, T., 2006) revealed that crickets can detect and respond to changes in the direction of the e-vector in natural situations. They successfully tested the animals with very small areas of polarized light resembling the natural situation of either vegetation blocking big areas of the sky or when the sky is mostly covered by clouds. Even elliptical polarization as encountered in hazy conditions is sufficient for detection.

But how do animals detect polarization? Photoreceptors are detectors of quanta, therefore a single photoreceptor cannot disentangle the very different properties of light, such as spectral content and e-vector orientation. The output of differently tuned receptors must be compared to access the e-vector orientation or color as we have already seen in Section 1.06.4.1.

The eyes of insects are inherently sensitive to polarized light because rhodopsin, the photoreceptor molecule, is orientated parallel in the microvillar membranes. Therefore light with an e-vector parallel to the microvillus axis is absorbed maximally (Israelachvili, J. N. and Wilson, M., 1976). Many insect species possess a small polarization-sensitive DRA used for detecting the direction of polarization. In the DRA, each ommatidium contains two polarization-sensitive photoreceptors with microvilli oriented orthogonal to each other (Labhart, T. and Meyer, E. P., 1999; Homberg, U. and Paech, A., 2002, Figure 18(b)). The ommatidia in the DRA exhibit several specific adaptations aiding polarization vision. In each ommatidium the photoreceptors come in two sets with microvilli oriented at roughly 90° to each other, thus being sensitive to mutually orthogonal e-vectors and subserving polarization antagonism. Also the microvilli are well aligned enhancing polarization sensitivity. In many insects the receptive field size of the ommatidia in the DRA is increased and the DRA is mainly directed upward and contralaterally (Labhart, T. and Meyer, E. P., 1999).

In the remaining eye the microvillar orientation along the rhabdomer is misaligned. This reduces or completely abolishes polarization vision and results in better brightness and color vision, because it maximizes the capture of photons. The main problem for color vision caused by sensitivity to polarized light, the false color problem (Wehner, R. and Bernard, G. D., 1993; Kelber, A., 1999b), is discussed by Vorobyev in the chapter Color in Invertebrate Vision. Takemura S. Y. and Arikava K. (2006) found that swallowtails might use a different strategy to reduce or even completely remove polarization sensitivity. In this species the R5–R8 photoreceptors that express identical spectral sensitivity are interconnected in each ommatidia; the authors discuss this as a possible way of removing polarization sensitivity.

Thus it seems as if insects trade off polarization vision and quality of color and brightness vision by compartmentalization of the eye, using one small region, the DRA, for the specialized task of navigation by polarized light. Similarly in lycosid spiders, only the most ventral part of the prinicipal eyes contains two types of photoreceptors that have mutually orthogonal microvilli and a gnaphosid spider has at least one pair of secondary eyes that can be used for polarization vision (Dake, M. *et al.*, 1999; 2001).

Polarization vision itself is monochromatic. The polarization sensors in the DRA are all of the same spectral type but might be sensitive to a different wavelength in different species. For example, the polarization sensors in honeybees (Labhart, T., 1980), desert ants (Duelli, P. and Wehner, R., 1973; Labhart, T., 1986), flies (Hardie, R. C., 1984; von Philipsborn, A. and Labhart, T., 1990), and monarch butterflies (Sauman, I. *et al.*, 2005) are UV receptors. In crickets and locusts, polarization vision is mediated by blue receptors (Labhart, T. *et al.*, 1984; Herzman, D. and Labhart, T., 1989; Eggers, A. and Gewecke, M., 1993), and the DRA in cockchafers is dominated by green receptors (Labhart, T., *et al.*, 1992). This wavelength specificity of polarization vision renders the polarization vision system insensitive to changes in the spectral composition of the stimulus.

1.06.4.2.3 Two theoretical models of e-vector detection

Kirschfeld K. (1972) outlined two theoretical ways to determine the e-vector orientation. A single receptor must be able to rotate so that its microvilli would be in different orientations to the stimulus. The receptor would be maximally stimulated when it would be orientated parallel to the e-vector orientation and minimally stimulated when it would be orthogonal. The output would then be a sinusoidal modulation with a maximum for the orientation in which the microvilli are perfectly aligned with the e-vector. The only invertebrate species that could in principle use this method would be stomadopods, because they can rotated their eyes in the required manner (Land, M. F. *et al.*, 1990). The second possible way for e-vector detection would be to use several

receptors all of which exhibit a different e-vector tuning and to compare their outputs. This method requires that (1) at least three receptors of the same spectral type but with different e-vector orientation tuning would be combined and (2) all the photoreceptors involved in the task are aligned in a common reference system. None of these requirements is fulfilled in the polarization-sensitive regions of insects. Thus, both theoretical methods of e-vector detection can be rejected.

1.06.4.2.4 Neuronal mechanisms

The physiological properties of polarization-sensitive neurons have been studied using intracellular recordings in crickets and locusts, with some additional studies in desert ants and cockroaches. Recordings were performed either in the medulla of the optic lobes (cricket: Labhart, T., 1988; Labhart, T. *et al.*, 2001; Labhart, T. and Meyer, E. P., 2002) or at the level of the anterior optic tubercle and the CC (locust: Vitzthum, H. *et al.*, 2002; Pfeiffer, K. and Homberg, U., 2003). All polarization-sensitive interneurons (POL) neurons reported so far respond with tonic spiking activity when illuminated with polarized light. Two different response types of POL neurons have been found: polarization-opponent POL neurons and nonopponent POL neurons. Optic lobe neurons in locusts and cockroaches are nonopponent POL neurons. They are maximally excited by a particular and preferred e-vector and do not respond to e-vectors that are perpendicular to their individual preferred e-vector orientation. But they do not show polarization opponency and are sensitive to changes in light intensity (Homberg, U. and Wuerden, S., 1997; Loesel, R. and Homberg, U., 2001).

Polarization-opponent responses are encountered in optic lobe neurons in ants (Labhart, T. 2000), POL1 neurons in the cricket (Labhart, T. 1988; Labhart, T. and Petzold, J., 1993), and CC neurons in the locust (Vitzthum, H. *et al.*, 2002). The polarization-opponent responses correspond to the orientation of the two e-vector analyzers in each ommatidium. These analyzers are arranged perpendicular to each other and provide the antagonistic excitatory and inhibitory input to the next level of interneurons.

The POL1 neuron of the cricket is the best-studied example of this type. These neurons show sinusoidal spiking activity changes, which are induced by changes in the e-vector orientation and by including excitatory and inhibitory components (Figure 18(c)). The polarization-antagonism in these cells generates a differential signal. This enhances the e-vector contrast and at the same time renders the cells insensitive to changes in the variation of absolute light levels, to unpolarized light, and to chromatic contrast (Labhart, T. 1988; 1996; Labhart, T. and Petzold, J., 1993). Three physiologically different but anatomically identical bilateral pairs of POL1 neurons in the cricket medulla have been characterized. Their tuning differs according to the preferred e-vector orientation relative to the longitudinal body axis of the animal (Labhart, T. and Meyer, E. P., 2002; rev.: Wehner, R. and Labhart, T., 2006).

In the locust, most recordings focused on neurons in the lower unit of the anterior optic tubercle and the lower division of the CC (Vitzthum, H. *et al.*, 2002; Pfeiffer, K. and Homberg, U., 2003). These locust midbrain neurons differ in their physiological properties from polarization-sensitive POL1 neurons in the optic lobes of crickets. Locust midbrain neurons show polarization opponency but also respond to unpolarized light. The second difference regards the visual field of the locust midbrain neurons. Some of these cells not only receive binocular input, which is never seen in cricket POL1 neurons, but they can also have much larger receptive fields. Lastly the locust midbrain neurons respond to a continuum of e-vector orientations and cannot be classified into distinct physiological classes (rev.: Homberg, U., 2004). Recently Heinze S. and Homberg U. (2007) showed that polarization-sensitive tangential neurons, TB1 neurons, which were recorded in the PB, have arborizations in a single column in each hemisphere of the PB. The PB has eight columns in the left hemisphere L1–L8 and eight columns in the right hemisphere R1–R8. The TB1 arborizations in the left and the right hemisphere are always eight columns apart, for example, R1/L8 or R2/L7. Intracellular recordings showed that the pattern of columns with branching corresponded to the physiological properties of the cells. Each TB1 neuron showed polarization opponency and their e-vector tuning revealed a linear relation to the position of their arborizations. The range of tuning maxima corresponds to the whole range of e-vector orientations that are possible under natural conditions. This means that the TB1 neurons establish an e-vector map in the PB.

In addition, recordings were made from three columnar cell types that are potentially postsynaptic to the TB1 cells. They are, like the TB1 cells, polarization-sensitive and also reveal a spatial map of e-vector tuning albeit shifted to the TB1 map. This

spatial representation of the e-vector shows an extraordinary level of organization. It should allow the locust to compute its head orientation as long as the animal can distinguish the solar from the antisolar hemisphere of the sky. These neurons provide information about the sun's azimuth and therefore are similar to an internal 180° compass.

Over the day the polarization pattern in the sky is changing. So how do insects adjust for this time-dependent change? This is one of the main problems that still needs to be addressed for understanding the use of polarization vision. Some experimental data suggest that the CC and a specific part of the medulla, the accessory medulla, might play a central role in this timing issue (Homberg, U., 2004).

1.06.5 Ocelli – Visual Information Processing on the Fast Track

Besides the compound eye, many flying insects employ a second visual system, the ocelli, contributing to the inner-loop control of gaze and flight stabilization. In fact it was already noted very early that among insects there is a high degree of correlation between bearing wings and possessing an ocellar system (Kalmus, H., 1945). Due to their design in terms of optics, signal integration, and conductance velocity, the ocelli work faster than the compound eyes and thus cover a higher dynamic range of attitude changes. In that respect they complement the inner-loop-related functions of those pathways receiving input from the compound eyes. In the early 1980s, Goodman L. J. (1981) provided a comprehensive review on the structure and the function of ocellar systems in several insect species. Although most research on the ocellar system so far has been done in orthoptera, recent developments on the convergent processing of ocellar signals and compound-eye-mediated information came from studies in flies.

1.06.5.1 Ocelli in Flies

The ocelli in flies are a set of three small single-lens eyes, which seem to be well adapted to detect rotations in the manner of an artificial horizon (Wilson, M., 1978a; Taylor, C. P., 1981a; 1981b; Schuppe, H. and Hengstenberg, R., 1993; Stange, G. *et al.*, 2002). The retina of each ocellus is attached to the rear surface of the lens resulting in a highly blurred image at the level of the photoreceptors, which is composed only of low spatial frequencies. There is no evidence that the ocelli make use of any remaining image structure but only integrate light levels across their entire visual fields with the exception of the ocelli in dragonflies (Berry, R. *et al.*, 2006).

The anatomy of the fly ocellar system has been described in quite some detail (Nässel, D. R. and Hagberg, M., 1985). Attached to the retinae of the ocelli is a fused first-order neuropil from where three different types of interneurons project through the ocellar nerve to various areas in the brain and to the thoracic ganglia. The blowfly *Calliphora* has got 12 large inteneurons, L-neurons, which are particularly conspicuous because of their enormous axon diameter. The interneurons of the second type, 10 M-neurons, have intermediate axon diameters and the third type consists of a greater number of S-neurons having small axon diameters. L-neurons project to the posterior slope of the lateral protocerebrum where the axons of output LPTCs terminate (see Section 1.06.3.1.3.(i)). M-neurons dispatch information to many areas including the pro- and mesothoracic ganglia, the lateral protocerebrum, the lobula, and to the ventral medulla. The latter projection is interesting since columnar elements in the ventral medulla mediate information from the ventral visual field where brightness levels are not very high compared to those the ocelli face dorsally. S-neurons project to regions in the posterior slope also receiving input from antennal mechanosensory fibers (Nässel, D. R. *et al.*, 1984), which were implied in measuring air speed (Burkhardt, D. and Schneider, G., 1957).

1.06.5.2 The Functional Role of the Ocelli

Ocelli are particularly effective in sensing rotations of the animal, crucial for proper gaze stabilization (dragonflies: Stange, G. and Howard, J. 1979; Stange, G. 1981; locusts: Taylor, C. P., 1981a; 1981b). Behavioral experiments in flies show the ocelli to contribute only to gaze stabilization (Schuppe, H. and Hengstenberg, R., 1993; rev.: Hengstenberg, R., 1993) but anatomical evidence in combination with electrophysiological findings suggests them to also support the fly's attitude control (see below).

Compared to the neural processing performed on compound eye input in the context of directional motion analysis (rev.: Reichardt, W., 1987; Borst, A. and Egelhaaf, M., 1993), wiring up an ocellar-based rotation detector would be relatively straightforward. L-neurons integrate the outputs of ocellar

photoreceptors and code light intensity fluctuations in terms of graded membrane potential changes (Wilson, M., 1978b; Simmons, P. J. *et al.*, 1993; Simmons, P. J., 1999). Although the exact neural mechanism is unknown yet, directly comparing the outputs of L-neurons would be sufficient to build a rotation detector. The diameter of L-neuron axons, the largest in the fly nervous system (Nässel, D. R. and Hagberg, M., 1985; Simmons, P. J. *et al.*, 1993), results in a particularly fast signal propagation. Altogether, the functional adaptations suggested for the ocellar system would facilitate fast motor responses: In the locust, stimulation of the ocelli requires only half the time to elicit compensatory head movements than compound eye stimulation does (Taylor, C. P., 1981a).

Though faster, ocelli-induced motor responses in dragonflies are jerkier compared to responses the compound eye mediates (Taylor, C. P., 1981a), which might as well be a general trend across species. The integration of compound eye and ocellar outputs may establish a system that visually detects rotations by combining high speed with high precision. At which stage and how compound-eye-mediated self-motion information provided by LPTCs (see Section 1.06.3.1.3.(i)) and the ocelli signals may be integrated is by and large unknown.

Anatomical and electrophysiological evidence suggests descending neurons connecting to various motor centers in the thoracic ganglia to be a major stage of multimodal integration (dragonfly: e.g., Olberg, R. M., 1986; Frye, M. A. and Olberg, R. M., 1995; locust: e.g., Burrows, M. and Rowell, C. H. F., 1973; fly: Strausfeld, N. J. and Bassemir, U. K., 1983; Strausfeld, N. J. and Gronenberg, W., 1990). The dendritic input arborizations of fly descending neurons in the lateral protocerebrum overlap with output terminals of both LPTCs and L-neurons (Strausfeld, N. J., 1976; Strausfeld, N. J. and Bassemir, U. K., 1983). This implies information about specific rotations the LPTCs encode (Krapp, H. G. and Hengstenberg, R., 1996; Krapp, H. G. *et al.*, 1998; see Section 1.06.3.1.3.(i)) and ocellar information to converge at the multimodal descending neurons.

1.06.5.3 Two Visual Mechanisms – One Motion Parameter

A recent electrophysiological study shows, however, that the spiking activity in the heterolateral LPTC V1 (rev.: Hausen, K., 1984; Krapp, H. G. and Hengstenberg, R., 1997; Krapp, H. G. *et al.*, 2001) is modulated by ocellar input (Figure 19, Parsons, M. M. *et al.*, 2006). How this sensitivity to ocellar stimulation in the V1 cell is established has not been clarified yet. One possible explanation is based on the fact that descending neurons and the LPTC subgroup of VS cells presynaptic to the V1 cell are connected via mixed chemical/electrical synapses (Strausfeld, N. J., 1976). Ocellar inputs to the descending neurons may change

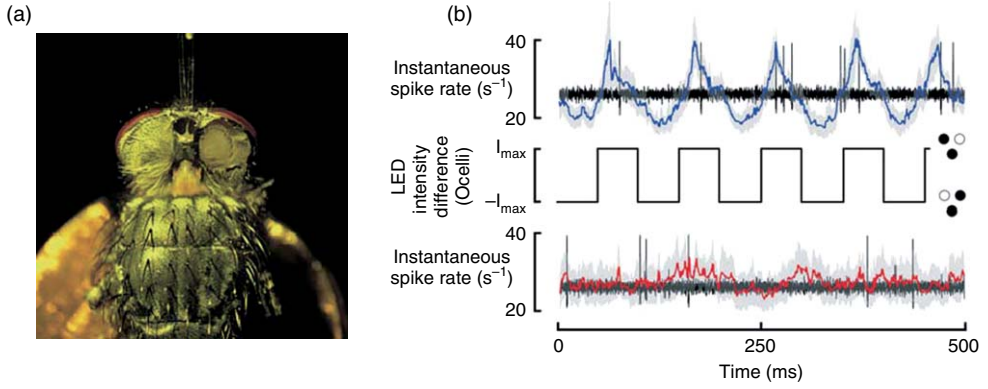

Figure 19 Ocellar-induced activity in lobula plate tangential cells (LPTCs). (a) Photograph taken from the rear of the fly showing the opened head capsule. Through the small hole in the middle the ocellar nerve connecting the ocellar neuropil, dorsal, with the protocerebrum. Through the hole on the right the lobula plate is exposed. (b) The upper panel shows an individual extracellular recording from the spiking V1 cell. Superimposed is the average response (blue line, $n = 563$, gray shaded area: $\pm$SEM) to alternating illumination of the left and right ocellus (middle trace). The ocellar stimulus clearly modulates the activity of the V1 cell. Cauterizing the ocellar nerve abolishes this effect. (red line, bottom panel). For further explanation see text. (a) Photograph courtesy of M. M. Parsons. (b) Adapted from Parsons, M. M., Krapp, H. G., and Laughlin, S. B. 2006. A motion-sensitive neurone responds to signals from the two visual systems of the blowfly, the compound eyes and ocelli. J. Exp. Biol. 209, 4464–4474.

the membrane potential in VS cells through the electrical synapses, which in turn modulate the activity in their postsynaptic target, the V1 cell (Parsons, M. M. *et al.*, 2006).

Such unusual pathway to establish the early convergence of compound eye and ocelli signals at the level of the LPTCs makes sense from the functional point of view: there is evidence from fly neck motor neurons recordings supplying the fly gaze stabilization system that LPTCs encode visual information in coordinates already adapted to the needs of the motor system (e.g., Huston, S. J., 2005; Huston, S. J. and Krapp, H. G., 2003). The impact of the ocellar signals on the LPTC activity could be interpreted as a weighting based on independent information about one and the same parameter: the animal's rotational self-motion. Recent studies show that the gradual modification of V1 cell activity by the ocelli follows a similar dependence on the mimicked rotation axis as the preferred axis tuning of the V1 cell upon wide-field motion stimulation of the compound eye. (Parsons, M. M., personal communication).

Behavioral experiments on the fly gaze stabilization system suggest that the contributions from the compound eye, the ocelli, and the mechanosensory halteres to compensatory head movements are scaled and then linearly combined (Hengstenberg, R., 1991; 1993). As far as the ocellar input is concerned these results were recently supported by an electrophysiological study on the integration properties of an individually identified descending neuron. In simultaneous double recordings it was found that the descending neuron indeed combines ocellar and LPTC signals in a linear way (Haag, J. *et al.*, 2007).

Even though our understanding of the functional organization of the ocellar system is certainly not yet complete the ocelli are a perfect model system to study a fundamental issue in neuroscience, multimodal integration (see Section 1.06.6). An ideal situation would be performing electrophysiological studies in behaving animals where the number of sensory mechanisms controlling distinct behavioral tasks is systematically reduced.

1.06.6 Multisensory Integration and Sensorimotor Transformation

From the previous section we know that visual systems in insects provide a great variety of information to the animals. Depending on the context in which particular aspects of visual information are needed, local signals may be selectively integrated to yield a parameter that can be used to support motor action. To successfully close the action–perception loop, however, nervous systems must solve two fundamental problems:

The first problem concerns the reliability of sensory information. Flies, for instance, when stabilizing their flight need to make sure that the information they have gathered reliably reflects changes in attitude, which require specific inner-loop reflex action. Another example concerns long-range localization of potential food sources – a behavioral trait that requires outer-loop control.

The second fundamental problem they cope with is the transformation of integrated sensory signals into patterns of motor commands, which generate an adequate behavior. In the following two subsections we will outline these problems by presenting a few selected examples and discuss potential strategies nervous systems have adopted to solve them.

1.06.6.1 Vision and Other Sense – Increasing the Reliability of Sensory Information

1.06.6.1.1 Multisensory contributions to inner-loop control

Local sensory signals are highly ambiguous. An activity change in a single photoreceptor could have been caused for many reasons. How the fly disambiguates local signals along its motion vision pathway to finally extract information about its self-motion was discussed in Section 1.06.3.1.3. On their own, however, not even the highly specific signals of the lobula plate tangential neurons LPTCs would be sufficient to guarantee perfect inner-loop attitude and gaze stabilization over the fly's entire flight envelope. Noisy signals as well as noisy processing within the visual system reduce the reliability at which the exact changes in flight attitude may be detected. At this end the evolution of the visual system has designed a couple of measures to overcome the noise problem by, for instance, implementing selective integration of local information, signal adaptation, and employing a population for sensing arbitrary rotations in space. What is the problem then?

The problem is that the fly's combination of possible translations and rotations, its flight envelop, drastically exceeds the dynamic range within which the visual system is able to reliably operate. Angular

velocities even higher than 3000° per second may still result in some responses in the LPTCs but their ability to indicate angular velocity changes and changes of the current rotation axis is greatly reduced in the high dynamic range. Also, the response delay within the directional motion pathway, i.e., the time it takes from onset of a stimulus until the first detectible change in LPTC activity, is greater than 20 ms. Compound-eye-mediated compensatory head movements require 30 ms to be executed. Such time delay might be too long for efficient inner-loop control when dealing with faster attitude changes. The dynamic range imitation is mostly given by the inherent properties of visual information processing, in general. The phototransduction mechanism in the periphery, though producing a high gain, is slow as it involves a cascade of biochemical processes (Chapter Phototransduction in Microvillar Photoreceptors of Drosophila and Other Invertebrates) each of which takes extra time to be completed. On top of it, processing directional motion requires additional time as we mentioned earlier already. As a result the visual system contributes most reliably to inner-loop control in the range of hundreds rather than thousands of degrees per second.

Self-motions at thousands of degrees per second are quicker and more reliably detected by mechanosensory systems. The fast response and sensitivity in mechanosensory systems is due to an immediate transduction mechanism. Physical forces directly open ion channels in a mechanoreceptor cell resulting in its immediate depolarization. In Diptera, during evolution the pair of hind wings, still present in more ancient species such as locusts and dragonflies, has turned into a powerful mechanosensory system, the halteres (Pringle, J. W. S., 1948). These tiny club-like structures move at the same frequency as the wings during flight but 180° out of phase. Halteres basically work like gyroscopes and by measuring Coriolis forces provide the animal with information about angular rotations (Nalbach, G., 1994; Nalbach, G. and Hengstenberg, R., 1994) within a higher dynamic range than LPTCs do. From the functional point of view halteres are equivalent to our vestibular system, which gives us information about fast postural changes and is heavily involved in controlling balance and gaze (e.g., rev.: Carpenter, R. H. S., 1988). Mostly due to the mechanosensory transduction mechanism, they employ both the vestibular system and the haltere system are not sensitive to slow attitude changes. The haltere system in flies performs best on angular rotations of a few thousand degrees per second and contributes strongly to gaze and flight stabilization. It is extremely fast as well. Haltere stimulation induces compensatory head movements within less than 10 ms.

The third sensory system that contributes to inner-loop control is the ocellar system (see Section 1.06.5). Even though depending on phototransduction, due to minimal processing and fast signal transduction the ocellar system has a comparatively short neural response delay of about 15 ms at the LPTCs level (Parsons, M. M. *et al*., 2006). As described in Section 1.06.5 the ocelli contribute to the phasic component of the dorsal light response, a postural reflex, that keeps the visual system aligned with the external horizon. Dorsal light responses are observed in a variety of lower vertebrates (von Buddenbrock, W., 1915; Meyer, D. L. and Bullock, T. H., 1977; rev.: Hengstenberg, R., 1993). This reflex has an additional tonic component, which, in flies, is mediated by the compound eye. The combined dorsal light reflex results in a behavioral output that is maximal for angular rotations at about 500° per second.

Using a behavioral paradigm Hengstenberg and colleagues systematically studied how the output of the different sensory mechanisms cooperate to support compensatory head movements in the fly (rev.: Hengstenberg, R., 1991; 1993). The major contribution of Hengstenberg's research was, firstly, to demonstrate that the dynamic ranges of the different mechanisms complement each other. And secondly, that in the fly the way the outputs from the different systems are combined seems to be surprisingly simple: The overall performance of compensatory head-roll movements is readily explained by the scaled sum of the outputs the different sensory mechanisms provide. (Figure 20, rev.: Hengstenberg, R., 1993). This result was true for both head movements as a function of time and as a function of angular velocity.

At least with respect to gaze stabilization, multisensory integration ensures that the entire dynamic range of attitude changes is covered by complementary sensory mechanisms. Each mechanism on its own has certain bandpass characteristics caused by the intrinsic properties of the respective sensory modality. At low angular velocities where the halteres do not respond above noise level, the ocelli and the compound eye take over. Conversely, the halteres provide reliable angular velocity information in a range too fast to be analyzed by any visual mechanism. Combining sensory mechanisms with overlapping and complementary dynamic ranges also benefits the reliability to detect changes in

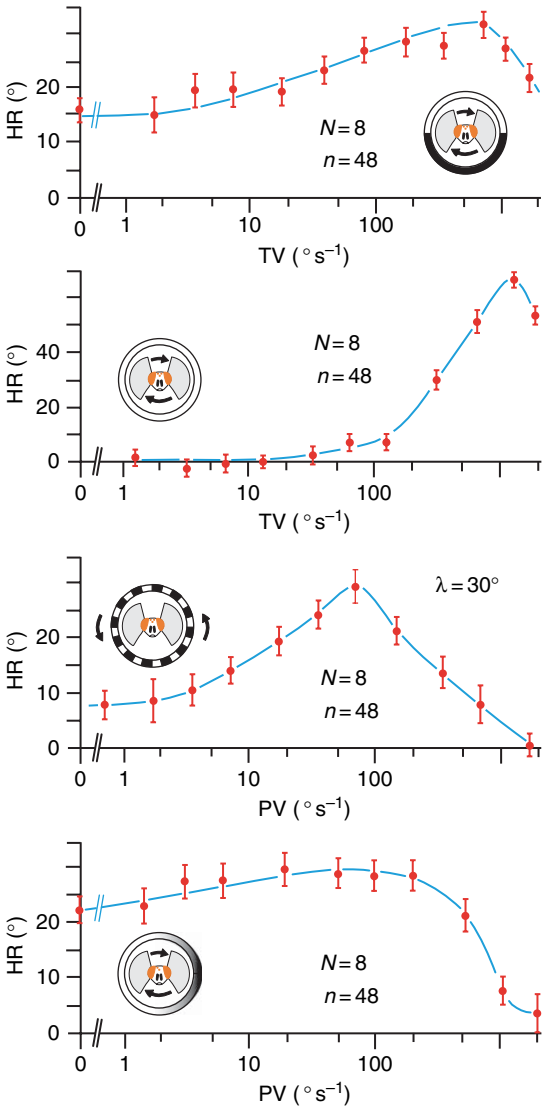

Figure 20 Multisensory integration in the gaze stabilization system of the blowfly. Different sensory systems contribute to compensatory head movements within different dynamic ranges. The head roll angel (HR) is plotted as a function of the angular velocity of the stimulus. In the top panel the total response is shown when the halteres, ocelli, and compound eyes contribute to the response. The second panel shows the haltere-mediated response, which peaks at about 1000° per second but hardly contributes to the low dynamic range. The third panel shows the contribution of directional motion mediated by the compound eye with a peak at about 100° per second. The phasic and tonic components of the dorsal light response, mediated by the ocelli and the compound eye, respectively, cover a wide range from DC stimulation up to stimulus velocities of about 500° per second (bottom panel). The overall performance of compensatory head roll (top panel) is very well explained by simply summing up the scaled outputs of the different sensory systems. TV, thorax velocity; PV, pattern velocity; λ, spatial wavelength of pattern. For further information see text. Redrawn from Hengstenberg, R. 1993. Multisensory Control in Insect Oculomotor Systems. In. Visual Motion and Its Role in the Stabilization of Gaze (*eds*. F.A. Miles and J. Wallman), pp. 5,285–298. Elsevier.

attitude: at whatever angular velocity a change in attitude occurs there will always be at least two independent mechanisms indicating it. This of course increases the reliability with which the magnitude of the change may be estimated.

Possible stages at which signals from the different sensory mechanisms may be integrated we mentioned in some of the previous sections already. In the ventrolateral protocerebrum the terminals of several classes of interneurons converge conveying

information from various sensory systems including the ocelli, the compound eyes, and the antennae (Strausfeld, N. J. and Bassemir, U. K., 1983; rev.: Strausfeld, N. J., 1976). In addition ascending neurons provide signals from the halteres and leg proprioceptors (rev.: Hengstenberg, R., 1991). Strong anatomical evidence suggests that descending neurons and neck motor neurons (NMNs) are among the prime target of multisensory integration. Consequently, descending neurons were found to respond to visual stimuli applied to the compound eyes and the ocelli (Gronenberg, W. and Strausfeld, N. J., 1990; Gronenberg, W. *et al.*, 1995; Haag, J. *et al.*, 2007) as well as mechanical stimulation of the halteres and other mechanoreceptors on the fly body (Gronenberg, W. and Strausfeld, N. J., 1990; Gronenberg, W. *et al.*, 1995). NMNs, which represent the final common pathway of the gaze stabilization system, also reflect multisensory integration. While some NMNs already respond to directional motion in small areas of the fly's visual field (Huston, S. J. and Krapp, H. G., 2003), others require visual wide-field stimulation (Milde, J. J. and Strausfeld, M. J., 1990, Huston, S. J., 2005). Huston S. J. (2005) studied the effect of combined haltere and compound eye stimulation on the response properties of NMNs. Intracellular recordings demonstrated a gating mechanism mediated by the halteres that enables visually induced spiking in NMNs. While visual stimulation alone only resulted in subthreshold excitatory postsynaptic potentials in some motor neurons, spiking was observed only when combined with haltere movements (Huston, S. J., 2005).

The evidence presented seems to be compatible with the common view that descending neurons and motor neurons are the sites of multisensory integration in the fly – most likely in the context of both gaze and flight stabilization. Recent findings suggest, however, that multisensory integration may take place even earlier in the motion vision pathway. Besides the results Parsons M. M. *et al.* (2006) provide on the modulation of the activity level in spiking LPTC V1 induced by ocellar stimulation (see Section 1.06.5) activity changes in the H1 cell upon air puffs delivered to the antennae and mechanical stimulation of the fly's abdomen were also observed (Laughlin, S. B., personal communication, Huston personal communication). In Section 1.06.6.2 we will discuss the potential significance of multisensory integration taking place already at the level of the LPTCs.

One of the next logical steps toward understanding the functional architecture of inner-loop control would be to create a conceptual model of multisensory gaze stabilization. It is still puzzling how several sensory mechanisms each of which operating best in a certain range of angular velocities and kicking in after different response delays manage to control the gaze without generating instabilities. Besides an anatomical description (Strausfeld, N. J., *et al.*, 1987) such model would require detailed knowledge about the dynamic and kinematic properties of the fly neck motor system, which – unfortunately – is not yet available.

1.06.6.1.2 Multisensory contributions to outer-loop control

In the previous section we outlined the significance of multisensory integration in the context of inner-loop control in flies where a fast and reliable response matters. Here we will give an example of how sensory information from different modalities may be combined for a specific outer-loop control task: long-range localization of attractive odor sources.

Recent experiments in freely flying *Drosophila* suggest that there is indeed a tight connection between anemotactic behavior, i.e., flying against with wind, olfaction, and vision. Without an odor presented in a wind tunnel experiment the flies show a trimodal trajectory distribution: a high proportion of trajectories is directed toward the wind but trajectories perpendicular to the wind direction induce two additional modes. The latter components may be explained by searching behavior while the dominant component indicates anemotaxis. Added odor abolishes the searching behavior and results in a focused average flight trajectory toward the odor source (Budick, S. A. and Dickinson, M. H., 2006). These findings imply that the combination of wind and odor facilitates steering maneuvers which keep the fly on a straight trajectory. This interpretation is supported by earlier experiments showing that *Drosophila* does compensate better for wide-field retinal image shifts when simultaneously presented with an attractive odor (Frye, M. A. and Dickinson, M. H., 2004).

These experiments in *Drosophila* demonstrates the importance of multimodal integration and also show that different sensory systems interact with each other to accomplish a goal-oriented behavior. How and where in the nervous system such integration is performed in *Drosophila* is not yet understood, though the involvement of MBs is likely as our next example implies.

1.06.6.2 The Relationship between Sensory Systems and Motor Systems: Strategies of Sensorimotor Transformation

Sensory signals are sampled in local coordinates, which are usually specified by the spatial arrangement and structural properties of the receptor cells. Mechanoreceptors, for instance, have a default activation plane defined by their functional morphology. Similarly, the neurons underlying the computation of directional motion correlate light intensities measured at neighboring ommatidia, which are arranged in the hexagonal lattice of the compound eye (see Section 1.06.3.1.2). Motor systems, however, employ coordinate systems defined by the pulling planes of the muscles. How is information obtained in various sensory coordinate systems transformed so that it is suitable to control movements in motor coordinates. In simple reflexes, for example, the knee jerk reflex, the sensory muscle spindle that measures changes in muscle length, is already aligned with the muscle it activates. In this case the sensorimotor transformation is basically inherent to the anatomical arrangement. Such coalignment was also shown in cases where different modalities use similar measuring axes to sense the same parameter but in complementary dynamic ranges. An example is the coalignment of the vestibular system and the preferred axes of visual neurons analyzing self-motions in pigeons (Wylie, D. R. *et al.*, 1998) and rabbits (Graf, W. *et al.*, 1983). But how the information is then transformed to control the respective motor plants is still unknown.

One possible way of achieving sensorimotor transformations involves an intermediate step that decomposes information encoded in sensory coordinates into independent components, which are then used to control the behavior. In the barn owl, for instance, Masino T. and Knudsen E. I. (1990) found that subsequent to the retinotopic code in the optic tectum and before the activation of the motor neurons, head movements are encoded in orthogonal components. Such an intermediate stage could be the target of different sensory modalities all of which sample information in their own local coordinate systems.

A possible approach to study sensorimotor transformations requires characterising the properties of neural elements at subsequent processing steps throughout a task-specific pathway. In the fly, electrophysiological experiments were performed on motor neurons innervating the animal's neck muscles controlling compensatory head movements (Strausfeld, N. J., *et al.*, 1987). These NMNs receive input from the lobula plate tangential cells (LPTCs) and from other sensory modalities (Milde, J. J., *et al.*, 1987, see Section 1.06.6.1.1). Based on the NMNs' responses to local directional motion their visual receptive fields could be characterized. Like LPTCs such as HS and VS cells, the NMNs show a distribution of local motion preferences and sensitivities that is similar to the structure of particular optic flow fields (Huston, S. J. and Krapp, H. G., 2003; Huston, S. J., 2005). From some recordings close to the neuromuscular junction, even the visual receptive fields of some neck muscles could be reconstructed. From the visual receptive fields the preferred rotation axis of each NMN was estimated as it was done previously for the VS and HS cells. Despite the fact that the NMN receptive fields show generally a higher degree of binocularity than the VS receptive fields do the preferred axis distributions of the two neural populations were correlated (Huston, S. J., 2005).

This finding has remarkable implications for the sensorimotor transformation in the fly gaze stabilization system. The fly seems not to employ an intermediate stage at which sensory information is decomposed into orthogonal components and then sent to the motor neurons as was suggested for the barn owl. Instead, information from the LPTC is merely combined from cells of both parts of the brain to increase the NMNs' specificity for particular self-rotations. Otherwise no obvious coordinate transformation seems to occur. This suggests that the population of output LPTCs already encodes visually derived information in a coordinate system that is closely related to the coordinate system the neck muscles use. Such simplified sensory motor transformation would be fast and – since no additional processing layer is required – also energy-efficient. The actual sensory motor transformation seems to take place already at the level of the LPTCs by selectively integrating local motion signals. The local preferred directions within the receptive fields of both LPTCs and NMNs reflect the organization of the local sensory coordinate system in the motion vision pathway. Their global properties, that is, their preferred self-motion axes, on the other hand, reflect the organization of the motor coordinate system. In particular the gaze stabilization system benefits from this computationally inexpensive conversion between sensory and motor coordinates. The neck motor system deals almost exclusively with rotational degrees of freedom to efficiently support visual processing. Rotation-

specific information that the population of LPTCs provides can therefore be used directly to control the gaze.

Such simplified sensorimotor transformation also makes sense in the context of multisensory integration. Once established a coordinate system compatible to the needs of the motor system can be used to integrate information about the same self-motion parameter but provided by other senses such as the halteres or the ocelli (see Section 1.06.6.1).

1.06.7 Visual Cognition

1.06.7.1 The Traditional View

The traditional way of thinking about arthropod or insect behavior and also the way we structured this chapter is to assume sets of mostly independent sensory–motor circuits, each of which is responsible for one particular task or behavior that the arthropod or insect is performing. For example, the visual flow field that is experienced during flight is used for flight stabilization. The information flow is thought to be mainly from the sensory input units vertically to the motor output sites, with little, if any, crosstalk with other sensory systems or other circuits that are processing information for different sensory–motor tasks. In most cases they are thought to consist of simple circuits of a few neurons or they can even be realized by single identified neurons.

Considering this traditional, widely held, and scientifically very well supported view of invertebrate processing, we should expect rather limited cognitive functions. Invertebrates should possess only specific adaptations to unchanging environmental conditions and behavioral tasks. But a closer inspection of sensory–motor circuits reveals substantial evidence for plasticity and cross talk between different control circuits as we discussed in earlier parts of this chapter. Additionally, invertebrates and insects in particular have adapted to all habitats and are evolutionarily extremely successful (Wilson, M. and Hölldobler, B., 1987). But this can only be explained if the insect brain is able to provide useful and adaptable solutions to a very wide range of ecologically relevant problems.

1.06.7.2 Arguments for Cognitive Functions in Insects

As more and more insects are studied in detail and in their natural habitats it becomes apparent that despite their relatively simple nervous systems, insects display a rich behavioral repertoire. Vision plays a major role in their ability to flexibly process information when adapting to their changing environment. As discussed above, the visual system of insects is characterized by a high temporal, though rather low spatial resolution compared to humans. This allows insects to analyze a variety of visual cues such as motion, color, and polarized light – to name just a few examples – in the context of outer-loop control, which they exploit to navigate, identify landmarks, and to detect mates or prey. But they are also capable of comparing current visual inputs to references previously stored in their memory. Thus, insects not only gather sensory information and use it in a predefined reflex-like way but also assess the information in a given behavioral context before they take appropriate action. In the following we will outline some experimental evidence for higher cognitive functions implemented in the insect brain.

1.06.7.3 Data Supporting Cognitive Functions

Two insect species are at the forefront of studies concerning more complex cognitive function, the fruit fly *Drosophila* and the honeybee. The honeybee can be studied in behavioral paradigms, which are akin to psychophysical tests in primates. They have a high capacity for learning in the context of foraging and navigation. Honeybees can be trained to perform rather complex tasks showing their impressive cognitive capacity. For example, honeybees can interpolate visual cues while navigating (Collett, T. S. and Baron, J., 1995). They can categorize and to a certain degree abstract visual information. This has been shown, for instance, by their ability to perceive and distinguish symmetrical from nonsymmetrical patterns (Giurfa, M., *et al.*, 1996) and by discriminating orientation during pattern recognition (van Hateren, J. H. *et al.*, 1990) or when learning flower-like patterns (Horridge, G. A. and Zhang, S. W., 1994). Bees can form sameness and difference concepts (Giurfa, M., *et al.*, 2001) by learning to solve delayed matching-to-sample tasks and delayed nonmatching-to sample' tasks (Figure 21). Bees exhibit associative recall during navigation (Zhang, S. W. *et al.*, 1999) and can even associate visual with olfactory information (Srinivasan, M. V., *et al.*, 1998). Bees were shown to learn contextual information (Collett, T. S. *et al.*, 1997) and are capable of communicating to their

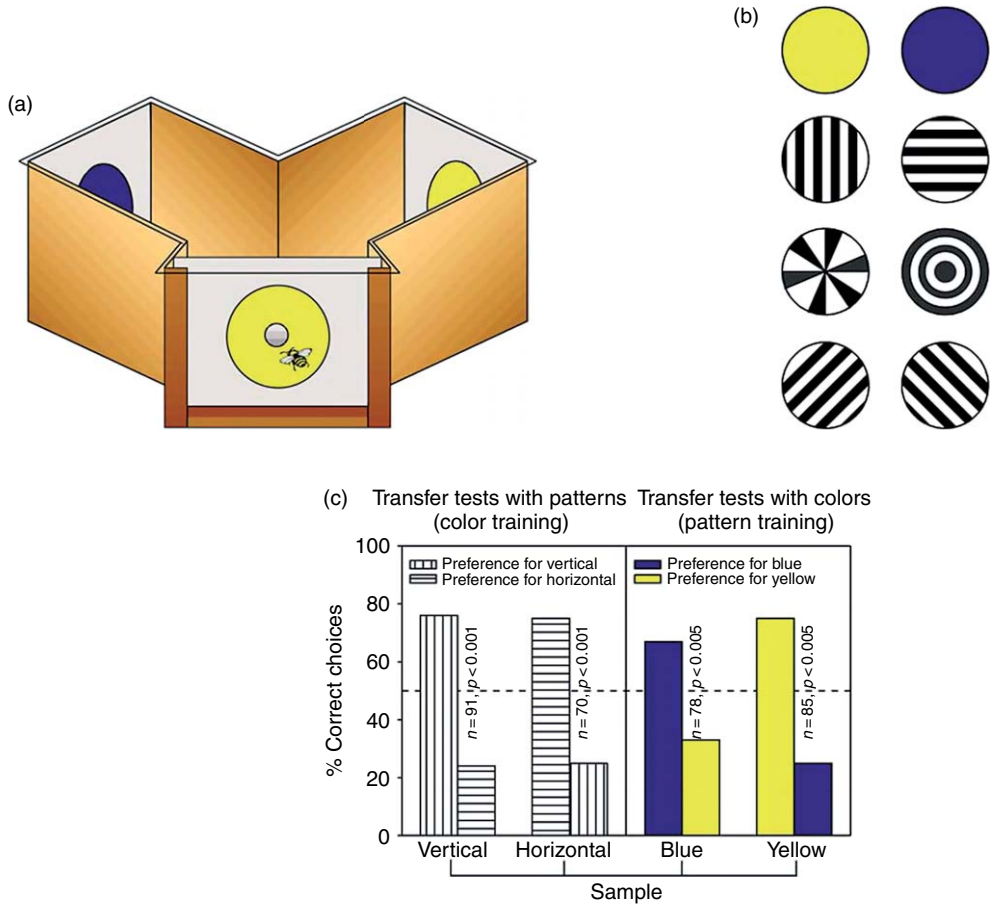

Figure 21 Visual cognition. (a) A y-maze is used for training and testing the bees in a delayed matching-to-sample procedure. This reveals whether bees can build a concept of sameness between stimuli, independent of which stimuli are used. Bees are presented with a sample and then with a set of stimuli including one stimulus that is identical to the sample. During training the bees are rewarded with sucrose solution if they always choose the stimulus that is identical to the sample despite the fact that the sample is regularly changed. The sample is presented at the entrance of the y-maze and the bees have to pass through the maze without being rewarded until they reach the back wall of the maze and choose the identical stimulus to the sample presented at the entrance. (b) Visual stimuli were used for training and testing the bees. In transfer test experiments, the bees were trained with colored disks and then tested with achromatic patterns that were novel to the bees and vice versa. (c) Performance levels of the bees in the transfer tests; the bees solved the problem for both transfer tests. Adapted with permission from Giurfa, M. 2003. Cognitive neuroethology: dissecting non-elemental learning in a honeybee brain. Curr. Opin. Neurobiol. 13, 726–735.

nest mates information about the location of a flower patch they have been visiting (von Frisch, K., 1967).

But honeybees are not alone in showing such capabilities. Fruit flies can perform associate (Wandell, S. and Quinn, W. G., 2001) and novelty learning (Dill, M. and Heisenberg, M., 1995) as well as contextual generalization (Liu, L. *et al.*, 1999). Next to behavioral, physiological, and molecular studies, which can be performed in bees as well, fruit flies permit genetic approaches also. All these techniques can be used to probe how complex cognitive functions are performed in the brain. Two examples for this are discussed here. Liu *et al.* (1999) show that individual flies can generalize their trained response to several other, different environmental contexts, in this case different lighting conditions. These changes in illumination did not affect the performance of the flies and this shows that context generalization guides this insect's learning. But when the authors eliminated the MBs, using three different techniques: (1) an *mbm* mutant lacking MBs, (2) selective pharmacological ablation using the cell poison hydroxyurea during the first larval stage, and (3) reverse genetic ablation by enhancer-driven tetanus toxin, they found that retention of the trained pattern was strictly bound to the context during learning. The

flies did not generalize to other contexts any more. Here the use of molecular techniques allows us to gain insights into the possible neuronal location of context generalization.

In another example the localization and the neuronal footprint of saliency and attention are probed. From behavioral tests it is apparent that insects apply different strategies depending on the salience of, and the attention toward, particular visual cues. Recent work by van Swinderen and Greenspan that combined a physiological and genetical approach gives the first physiological evidence on this cognitive function. They recorded local field potentials (LFPs) in the *Drosophila* brain and were able to show a change in the 20–30 Hz range of the LFP when visual stimuli presented to the fly were made more salient. The saliency levels were changed by combining the visual stimuli with an olfactory stimulus, heat, or through novelty. van Swinderen and Greenspan used saliency-inducing stimuli, which had been found to change the saliency of stimuli in behavioral experiments in *Drosophila* (olfaction: Guo, A. and Götz, K. G., 1997; heat: Wolf, R. and Heisenberg, M. 1991; orientation and shape: Mimura, K., 1982).

Insects are thus very suitable models for studying cognitive functions. They not only fulfill the criteria regarding the behavior complexity, but they are also amenable to quantitative experimental analysis. Most importantly, as apposed to vertebrates, insects lend themselves to molecular, genetical, and physiological studies of cognitive functions because of their well-characterized nervous system.

1.06.8 Conclusions

There is no doubt that over the past couple of years a great step forward has been made in understanding the processing of visual information in invertebrate, namely in insects. Several factors did contribute to this remarkable advance. Most of all it was the possibility to quantitatively describe the performance of specific behavioral tasks followed by a rigid characterization of the underlying neural circuits. Together, and in combination with analytical and numerical modeling, these approaches were tremendously successful in bridging the gap between neural processing and behavioral control. In addition, fundamental constraints were taken into account under which neural information processing takes place. The optimization of neural circuits was put into perspective by considering the cost of information in terms of energy consumption (Laughlin, S. B. *et al.*, 1998). It was also realized that visual information processing in insects is not confined to the laboratory environment but takes place in habitats where natural image statistics play an important role in tuning neural circuits to specific functions (Laughlin, S. B., 2001).

At the same time a promising trend has emerged challenging the traditional boundaries between different areas in neuroscience: General principles in sensory information processing are quantitatively linked more tightly to the kinematic and dynamic properties of the actual motor systems they control (Taylor, G. K. and Thomas, A. L., 2003). It is quite reasonable to assume that the operational constraints at the level of sensory and motor systems influence each other on a phylogenetic as well as on an ontogenetic timescales. Considering such parallel evolution may explain the functional organization of both systems more adequately compared to the classical attempt to understand their specific design principles in isolation.

A comprehensive understanding of visual information processing and its significance for the control of distinct behaviors also requires us to cross border between individual modalities and model systems. Multisensory integration, or – more technically – multisensor fusion, is another example. Studying the contributions that various modalities make toward the control of a specific behavior may help us to identify not only general principles in sensory information processing but also modality-specific adaptations. A similar rational motivates the comparison between the functional organization found in sensory systems of vertebrates and invertebrates.

Closely related to multisensory integration is the question of how visual information – or sensory information in general – is transformed into patterns of motor activity. The transformation was thought to takes place at descending neurons or at the motor neurons, also known as the final common pathway. Obviously, independent of the behavior that is controlled, both multisensory integration and sensorimotor transformation must have been completed at the motor neuron level the latest. In most species descending neurons and motor neurons show – unsurprisingly – highly complex response properties, which make them difficult to study. As a result, the actual transfer functions between sensory and motor neurons are mostly unknown. For the lack of experimental data, many models relate

sensory signals to the motor output only by approximating transfer functions and motor system properties. The predictive power of these models can be remarkably high in terms of explaining a specific behavior even if only one modality was considered to control it. Consequently, the question of how different behavioral tasks are actually coordinated and how they depend on the integration of multimodal information has – quite understandably – not been particularly popular over many years. The focus and the success in studying the neural circuits underlying individual aspects of visually guided behavior allow us now to proceed to the higher integrative systems level.

How are inner-loop reflexes and voluntary outer-loop modifications combined at the neuronal level to guarantee both flight stability and, for instance, a successful chasing flight? Does the insect visual system use efference copies to differentially read out optic flow information that lobula plate tangential cells provide during different flight phases? How is information obtained about different visual qualities and which is processed along separate pathways integrated to decide whether or not a particular flower should be approached? How is the continuous change in sun position compensated for in insects using polarized light patterns for navigation – and how does the polarization vision system modify inner-loop control? And finally – how are prior experience and cognitive aspects integrated to modify the neuronal processes underlying behavioral control?

This list of questions is far from being complete. In any case – how should we approach these questions? Besides further integrative experimental studies to specify, extend, and combine our existing models a test bed will be needed for their validation. The most rigorous test a model could be subjected to would be integrative hardware simulations. Such approach may be realized in a modular way, first testing simple control structures based on just one sensory modality. Then the hardware simulations may be increased in complexity by adding more modalities and the potential of including prior knowledge as well as plastic properties of the control circuits. It would be quite interesting to see what emergent features result as the level of integration is increased. Such system to test functional principles of sensory information processing discovered in insects may as well turn out to become a useful platform to assess the potential of small animals to address big questions in neuroscience.

Glossary

color Color is that aspect of visual perception by which an observer may distinguish differences between two structure-free fields of view of the same size and shape, such as may be caused by differnces in the spectral composition of the radiant energy concerned in the observation (Wyszecki, G., and Stiles, W.S., 1982).

1.07.1 What Is Color Vision?

What do we mean when we say that invertebrates have color vision? By definition, a human observer is assumed to have color vision if he can discriminate light stimuli of different spectral composition using cues other than their intensity (e.g., Wyszecki, G. and Stiles, W. S., 1982). Accordingly, we assume that an animal has color vision, if it can discriminate two light stimuli of different spectral composition (but equal in polarization) and continues to discriminate them when the intensity of the stimuli are varied, that is, these stimuli cannot be matched by adjusting their intensity. The first animals demonstrated to have color vision were invertebrates. Lubbock J. (1888) showed that a water flea *Daphnia*, which is positively phototactic, prefers yellow light to white light of a higher intensity. Some time later, von Frisch K. (1914) showed that honeybees could discriminate colored stimuli from various shades of gray. Since these pioneering studies, color vision has been demonstrated using behavioral experiments in a variety of invertebrates, including mites, spiders, crustaceans, and insects (for review see Kelber, A. *et al.*, 2003; Kelber, A., 2006).

Color vision is achieved by comparing the signals of photoreceptor cells sensitive to different parts of the spectrum. Anatomical and physiological studies show that the majority of invertebrates with eyes also have multiple spectral types of photoreceptors (Kelber, A. *et al.*, 2003). However, multiple spectral types of photoreceptors do not necessarily infer color vision – different spectral receptor types can be used for different purposes at different behaviors, giving receptor-specific (or wavelength-specific) behavior rather than color vision (Menzel, R., 1979). Receptor-specific behavior does not require the comparison of signals from different receptors and, therefore, is color blind. Animals that do have color vision can also show receptor-specific behavior in particular tasks. For example, a honeybee uses color vision for discriminating objects at close range (von Frisch, K. 1914, for reviews see Menzel, R., 1979; Menzel, R. and Backhaus, W., 1991), but it uses only a long-wavelength-sensitive photoreceptor for discriminating objects from far away and for motion vision (Srinivasan, M. V. and Lehrer, M., 1984; Giurfa, M. *et al.*, 1996; 1997). It is important to note that, while animals with multiple receptors can, in theory, be color blind in all behavioral contexts, such color blindness has not been revealed behaviorally in any animal so far tested.

1.07.2 Color Vision and Color Blindness in Different Eye Types

Eye design in invertebrates is diverse and gives rise to a variety of color-vision systems. Simple camera-type eyes, similar in plan to the vertebrate eye, are common in cephalopods and spiders. Compound eyes made up of many units called ommatidia are found in many insects and crustaceans (Land, M. F. and Nilsson, D.-E., 2002). The two types of eyes may coexist within the same animal, for example, insects have large compound eyes, which provide spatial, color, and polarization vision, and small camera-type eyes called ocelli. Ocelli detect overall illumination rather than form an image. Interestingly, physiology suggests that ocelli are capable of providing information about color without being able to resolve spatial details (Ruck, P., 1965; van Kleef, J. *et al.*, 2005). Usually, camera-type eyes have a better resolution than compound eyes (Land, M. F. and Nilsson, D.-E., 2002). The tiny (0.8 mm in diameter) camera-type eyes of the jumping spider *Portia fibriata* have an optical resolution only five times worse than ours and more than five times better than that of the best insect, a dragon fly (Land, M. F. and Nilsson, D.-E., 2002). These eyes allow spiders to locate prey with remarkable precision and provide spiders with a sense of color (Land, M. F., 1985; Nakamura, T. and Yamshita, S., 2000). The largest camera-type eyes are found among cephalopods (Land, M. F. and Nilsson, D.-E., 2002). While cephalopods have excellent spatial vision, they typically have only one type of visual pigment and, therefore, are color blind. The absence of color vision in cuttlefish and octopus has been questioned, because these animals can adjust body patterns, to match backgrounds consisting of differently colored natural objects, such as stones, sand, and algae. However, it appears that the match is achieved on the basis of brightness cues. When exposed to a background consisting of yellow and blue stones that are matched in brightness for cuttlefish eyes, cuttlefish ignore the difference in color (Marshall, N. J. and Messenger, J. B., 1996; Mathger, L. M. *et al.*, 2006) (Figure 1).

Surprisingly, the most sophisticated color vision may be associated with the low-resolution compound eyes of ancient marine crustaceans – mantis shrimps (stomatopoda). Mantis shrimps have 16 spectral types of photoreceptors, 12 of which are used for color vision including ultraviolet, the remaining four are used for spatial and polarization vision (Marshall, N. J., 1988; Cronin, T. W. and Marshall, N. J., 1989; Marshall, N. J. and Oberwinkler, J., 1999). The 12 types of spectrally different photoreceptors are located in a narrow strip across the eye – the midband – where photoreceptors used for color vision are combined in the top four rows of ommatidia (Figures 1 and 2). Each of these rows contains a ultraviolet (UV)-sensitive photoreceptor and two spectral types of photoreceptors sensitive in the visible range (Cronin, T. W. and Marshall, N. J., 1989; Marshall, N. J. and Oberwinkler, J., 1999). To be able to register colors of objects in the environment outside this very narrow strip, mantis shrimps move their eyes and scan midband photoreceptors over the image (Land, M. F. *et al.*, 1990). Such scans indeed allow shrimps to discriminate colored containers with food from gray containers of different shades (Marshall, N. J. *et al.*, 1996).

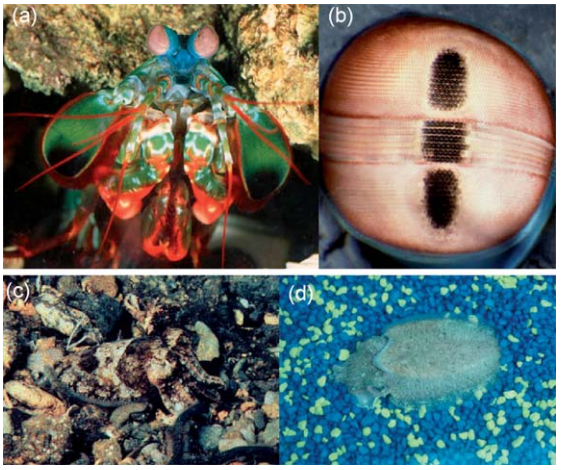

Figure 1 An animal with sophisticated color vision, mantis shrimp *Odontodactilus scyllarus* (a) and a color-blind cephalopod – cuttlefish *Sepia officinalis* (c, d). The frontal eye of a mantis shrimp (b) has a conspicuous stripe of facets – the midband. The four upper rows of the midband are specialized for color vision, its rows contain 12 spectral types of photoreceptors cells (Figure 2(b)). Color-blind cuttlefish is a master of camouflage – it matches texture, brightness, and color of the substrate – (c) but it fails to imitate the texture of yellow and blue gravel that is matched in brightness for the cuttlefish eye (Marshall, N. J. and Messenger, J. B., 1996). Photographs are courtesy of Justin Marshall and Roger T. Honlon.

1.07.3 Spectral Sensitivities of Invertebrate Photoreceptors

Visual pigments of all animals are constructed from a carotenoid chromophore bound to an opsin protein. In invertebrates, three types of chromophores are

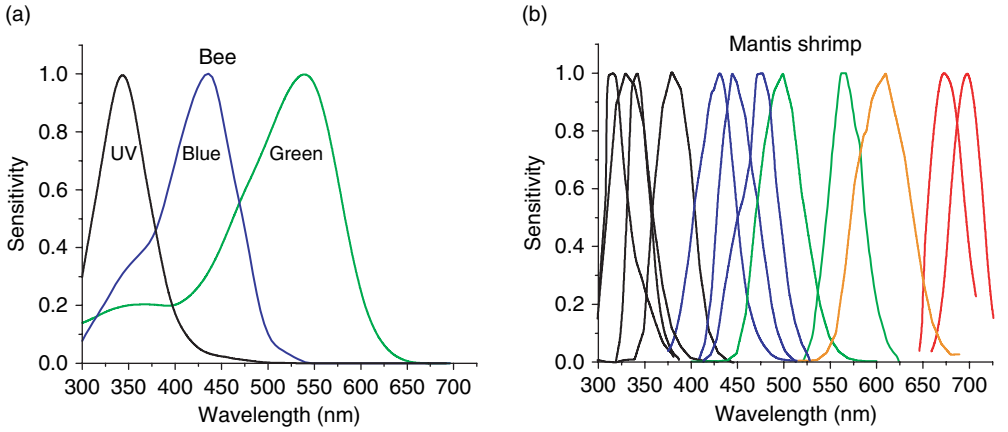

Figure 2 The spectral sensitivities of a honey bee, *Apis mellifera* (Menzel, R. and Backhaus, W., 1991) and of a mantis shrimp, *Neogonodactilus oesredii* (Marshall, N. J. and Oberwinkler, J., 1999). In a mantis shrimp, the narrowing of the spectral sensitivities is achieved by intrarhabdomal filtering.

found: (1) retinal, a chromophore found in terrestrial and marine vertebrates, is also found among cephalopods, crustaceans, and in insects such as bees and locusts; (2) 3,4-didehydroretinal, a chromophore typical of freshwater fish and amphibians, is present in several species of squid; (3) 3-hydroretinal, which is common in flies and butterflies (Vogt, K. and Kirschfeld, K., 1984). This chromophore is not found among vertebrates (for reviews see Kelber, A. *et al.*, 2003; Kelber, A., 2006). Generally, color vision is achieved by expressing different opsins in combination with the same chromophore to generate visual pigments with different sensitivities. However, some cephalopods, such as the firefly squid, *Watasenia scintitalis*, have three visual pigments probably derived from one opsin protein and three different chromophores (Seidowu, M. *et al.*, 1994). It remains unclear whether these visual pigments are used for color vision.

The spectral sensitivity of invertebrate photoreceptors often deviates substantially from the absorption spectrum of visual pigments. In the compound eyes of insects and crustaceans, rhabdomeric photoreceptors with different visual pigments are usually fused into a common light guide. This leads to mutual filtering of light and narrowing of receptor spectral sensitivity even in the absence of additional filtering pigments (Snyder, A. W. *et al.*, 1973). In the tired retina of the frontal eyes of a jumping spider, and in many insects and crustaceans, distal rhabdoms filter the light reaching the more proximal ones. However, the most prominent modification of spectral sensitivity is achieved by using additional pigments, which act as filters narrowing the spectral sensitivity, or transfer energy to the visual pigment, thus broadening the spectral sensitivity (for review see Douglas, R. H. and Marshall, N. J., 1999). The broad spectral sensitivity of the R1–R6 photoreceptors in the house fly is achieved by sensitizing pigment 3-hydroxyretinol (Vogt, K. and Kirschfeld, K. 1984). The same molecule serves as a screening pigment in a moth *Papilio*, where it narrows the spectral sensitivity (Arikawa, K. *et al.*, 1999). Perirhabdomal pigments change the spectral sensitivity of thin rhabdoms by lateral filtering. For example, the red perirhabomal pigment of *Papilio* shifts significantly the peak of the red pigment to the longer wavelength (Arikawa, K., 2003). In mantis shrimps, intrarhabdomal pigments create narrow spectral sensitivities, thus enabling color vision with 12 spectrally distinct photoreceptors. Interestingly, the spectral transmission of filters in the eyes of mantis shrimps changes as an adaptation to the light environment (Cronin, T. W. *et al.*, 2001).

1.07.4 Color Vision in the Darkness

In dim light, the signal-to-noise ratio of photoreceptor cells is low, which leads to an unreliability of color vision in darkness (for review see, Osorio, D. and Vorobyev, M., 2005). Accordingly, vertebrates use one spectral type of rods for scotopic vision and are color blind in dim light (but see Kelber, A. and Roth, L. S. V., 2006). However, invertebrates do not have a separate set of photoreceptors for nocturnal

and diurnal vision. Moreover, nocturnal insects, like hawkmoths, have several spectral types of photoreceptors in their eyes. It appears that nocturnal hawkmoths use color vision at light intensities where we use rod vision only (Kelber, A. *et al.*, 2002). To achieve reliable color discrimination, these insects must sum signals of many ommatidia and in doing so sacrifice spatial resolution. It remains unclear whether other insects that are active at night, such as nocturnal bees, retain their ability to discriminate colors in darkness.

1.07.5 Interaction between Color and Polarization Vision

The rhabdomeric photoreceptors of arthropods and mollusks are inherently polarization sensitive by virtue of their microvillar design (Land, M. F. and Nilsson, D.-E., 2002). Because a single polarization-sensitive photoreceptor cannot distinguish between the orientation of polarization and the spectral composition of light, the neural signals caused by changes in polarization cannot be distinguished from those caused by the change of spectral composition of light. Thus, polarization vision may be mixed with color vision inducing false colors, as has been shown for a butterfly *Papilio augeus* (Kelber, A., 1999). Because *Papilio*'s blue receptors are maximally sensitive to vertically polarized light, whereas green receptors are maximally sensitive to horizontally polarized light, the horizontally polarized light induces a sensation indistinguishable from green light. Papilio prefers to lay eggs on green surfaces to blue ones. It also prefers horizontal polarization to vertical polarization, indicating that polarization and color vision are mixed (Kelber, A., 1999). However, in the majority of insects and crustaceans, polarization vision is separated from color vision. In many insects, this is achieved by twisting photoreceptors along their longitudinal axis in such a way that microvilli of individual rhabdomers are not aligned (Wehner, R. and Bernard, G. D., 1992). For example, the honeybee eye is composed of twisted photoreceptors except for the uppermost dorsal rim of the eye (Wehner, R. *et al.*, 1975). In mantis shrimps, the polarization-sensitive parts of eye are spatially separated from the color-sensitive rows of the midband (Land, M. F. and Nilsson, D.-E., 2002) (see Figure 1).

1.07.6 Spatial Resolution of Color Vision – Random Arrangement of Photoreceptors in Compound Eyes

In our eyes, each photoreceptor cell samples a different point in the space. Since the receptive fields for color should include different spectral types of photoreceptor cells, the random distribution of cones in the human retina leads to a poor spatial resolution of chromatic vision (for review see Lee, B. B., 2004). However, because in compound eyes the rhabdomers are fused together into a common light guide, such eyes theoretically allow for higher spatial resolution of color vision, by virtue of locating all spectral types of receptors within each ommatidium. Early studies in the honeybee eye suggested that each ommatidium contains all three spectral types of photoreceptor (UV, blue, and green), indicating that insects have an eye design that optimizes the spatial resolution of color vision (Gribakin, F. G., 1969). This conclusion has been challenged recently by the discovery of a random arrangement of receptors with different spectral sensitivities first in a butterfly (Arikawa, K. and Stavenga, D., 1997) and later in the honeybee (Wakakuwa, M. *et al.*, 2005). Thus, it seems that the random arrangement of photoreceptors is a general pattern characteristic of insect color vision, predicting a significantly poorer resolution for color than for luminance vision.

1.07.7 Separation of Chromatic and Achromatic Vision

In humans, the chromatic aspects of color (hue and saturation) remain largely invariant when the intensity of a light stimulus varies. However, because color vision can be achieved by neural mechanisms that are sensitive to changes in light intensity (Brandt, R. and Vorobyev, M., 1997), animals that evolved color vision independently from the ancestors of humans can process color by neural mechanisms that do not permit separation of chromatic and achromatic vision. Therefore, invertebrates may have color vision that differs substantially from ours. Interestingly, behavioral experiments reveal striking similarities between color coding in bees and humans. Similar to humans, bees have three spectral receptor types, all of which are used for chromatic vision that is not sensitive to changes in stimulus intensity (Menzel, R., 1979; Menzel, R. and

Backhaus, W., 1991). Bees also have achromatic vision, which is mediated by their green receptor alone (for review see, Giurfa, M. and Vorobyev, M., 1997). In bees, as in humans, the spatial resolution of achromatic vision is better than that of chromatic vision. Bees detect and discriminate large stimuli (subtended angle >15°) on the basis of chromatic cues alone (Giurfa, M. *et al.*, 1996; 1997), whereas small stimuli (subtended angle <15°) are detected and discriminated on the basis of achromatic cues alone (Giurfa, M., and Vorobyev, M., 1998). Low spatial resolution may be a general feature of chromatic vision, because the signal-to-noise ratio can be improved by spatial summation of receptor signals. Indeed, comparisons of physiological recordings of receptor noise with behavioral thresholds shows that honeybees sum signals of individual photoreceptor cells to improve the signal-to-noise ratio (Vorobyev, M. *et al.*, 2001). The random arrangement of receptors may be a consequence of the low spatial resolution of chromatic vision, because there is no selective advantage in arranging all spectral receptor types within one ommatidium, if the receptive field for chromatic vision summates signals from many ommatidia. On the other hand, where receptors are arranged randomly in the retina, chromatic vision must utilize signals averaged over large areas. It remains unclear whether the separation of chromatic and achromatic vision is widespread among invertebrates.

1.07.8 Why Color Vision?

Color vision is useful for many tasks, and it is difficult to pinpoint one particular reason for the origin of color vision in animals (Vorobyev, M., 2004). However, two hypotheses explaining the origin of color vision have been widely discussed in the literature.

1. Color vision could have appeared as a general adaptation for seeing objects in conditions of patchy and changing illumination (Rubin, J. M. and Richards, W. A., 1982; Maximov, V. V., 2000). Since shadows yield strong variations in the intensity of illumination, achromatic vision is unreliable. Chromatic signals provide much more information about object material and can be used for reliable discrimination of objects from their backgrounds.
2. Color vision could have appeared as a specific adaptation for looking at colorful signals of plants and animals, which in turn could have coevolved with color vision. In the late nineteenth century, a prominent Canadian writer, Grant Allen, summed up the coevolution hypothesis for the origin of color vision in the following condensed formula: "Insects produce flowers. Flowers produce the colour-sense in insects. The colour-sense produces a taste for colour. The taste for colour produces butterflies and brilliant beetles" (Allen, G., 1879).

A number of studies of flower colors and insect vision have been inspired by this hypothesis of coevolution of flower colors and insect vision (e.g., Chittka, L. and Menzel, R., 1992). However, the analysis of spectral sensitivities of insects and crustaceans does not support this hypothesis (e.g., Vorobyev, M. and Menzel, R., 1999; Briscoe, A. D. and Chittka, L., 2001). In particular, it appears that the photoreceptors in flower foraging bees are practically identical to those in predatory wasps (Peitsch, D. *et al.*, 1992). Therefore, it is more likely that flowers exploited the preexisting color vision systems, which could have evolved for general tasks such as detection and identification of a variety of objects in conditions of patchy and changing illumination (Maximov, V. V., 2000; Vorobyev, M., 2004).

Glossary

accommodation The process of focusing in an eye, normally producing a sharp image of an object at a given distance.

acute zone A region of a compound eye where ommatidia are aligned so as to sample the visual field unusually densely. Analogous to the fovea of a lens eye.

chromophore A molecule attached to a protein which gives it a color. In visual pigments, this is a derivative of vitamin A or a similar compound and is the component that gives the visual pigment the ability to absorb visible light and to initiate changes in the protein that ultimately generate a neural signal.

dark noise Refers to events that occur in photoreceptors that mimic the absorption of light but are caused by other processes, typically by thermal events in visual pigments.

dichroic The property of a substance or structure to absorb one plane of polarized light preferentially to others. Visual pigments are naturally dichroic, which is the basis of most polarized-light sensitivity.

dichromacy Refers to color-vision systems that have two spectral classes of photoreceptors.

dioptric apparatus The optical elements of an eye, typically consisting of apertures, pigment layers, lenses, and possibly mirrors.

F-number A measure of the light-gathering ability of an optical device, given as aperture divided by focal length. The lower the *F*-number, the brighter the image on the retina.

irradiance The amount of light falling on a surface, typically as photons per unit time and area.

lambda-max (λ_{max}) Refers to the wavelength of maximum absorption of light (typically by a visual pigment) or sensitivity to light (typically by a photoreceptor).

ommatidium The unit of a compound eye, consisting of a group of photoreceptors and associated optical and supporting elements.

opponent channel A neural output that is derived by subtracting two inputs. In vision, these can be spatially, spectrally, or polarizationally different inputs. Opponent channels tend to enhance contrast in the signal.
opsin The protein component of a visual pigment, which binds the chromophore. All opsins of animals arise from a common ancestor and have many functional similarities across species.
optokinesis A class of eye movements in which the eye smoothly follows a visual scene or field, with intermittent rapid movements in the opposite direction.
optokinetic nystagmus The saw-tooth-like movements generated during optokinesis, created by alternating smooth, slow movements and saccadic movements in the opposite direction.
refractive index Refers to the ability of a substance to bend, or refract, light. Given as the ratio of the speed of light in the substance to the speed of light in a vacuum.
photopic Refers to vision in bright light. In vertebrates, cones are responsible for photopic vision.
photopigment See 'visual pigment'.
polarization (of light) Refers to the property of a beam or ray of light that results from the orientations of electric vectors (*e*-vectors) of the photons making up the beam. If the *e*-vectors are all parallel, the beam is fully linearly polarized; if these vectors are random in orientation, the beam is depolarized; if the situation is intermediate to these extremes, the beam is partially linearly polarized.
radiance The amount of light arriving from a location, within a solid angle, given as photons per unit time, area, and steradian.
retina An array of photoreceptors arranged in a sheet, hemisphere, or line. The retina can include neural elements besides photoreceptors in many cases.
rhabdomeric photoreceptor Refers to a photoreceptor cell in which the visual pigment is found in a large number of microvilli. This is one of the two great classes of photoreceptors, found primarily in invertebrates; the other is the ciliary photoreceptor type, found mainly in vertebrates.
saccade A rapid eye movement. Saccades occur during some visual tracking, during fixation movements of eyes, during inspection of a scene, and during the flickback movement phase of optokinetic nystagmus.
scotopic Refers to vision in dim light. In vertebrates, rods are responsible for scotopic vision.
structural color A color that is produced by optical phenomena arising from the microstructure or nanostructure of an object or surface. Many violet, blue, and green colors of animals are structural in origin.
summation The adding together of neural elements to generate a stronger or more robust signal. In vision, receptor inputs can be summed from a greater retinal area (spatial summation) or over greater amounts of time (temporal summation).
tapetum A reflecting layer behind the retina or at the base of an ommatidium. It serves to increase the amount of light passing through the retina and also generates eyeshine.
tetrachromacy Refers to color-vision systems that have four spectral classes of photoreceptors.
trichromacy Refers to color-vision systems that have three spectral classes of photoreceptors.
veiling radiance The light introduced between an object and an eye viewing it by scattering, typically within fog or underwater. Veiling radiance produces a bright haze which obscures objects behind it.
visual ecology The study of the adaptations of eyes of animals for their required functions.
visual pigment The molecules in photoreceptor cells that absorb light and begin the process of vision. They are invariably built from a protein, opsin, plus a chromophore, a derivative of vitamin A or a similar compound. Also called photopigment.

1.08.1 Introduction to Visual Ecology

Visual ecology is the study of the adaptations of eyes of animals for their required functions. Visual ecologists are concerned with how animals use their eyes, with the environments where their vision takes place, and with the visual objects that these animals are particularly interested in. Obviously, the field is unusually integrative and multidisciplinary in its approach. It considers the properties of light

(including its sources, distribution, and temporal features), how light is modified as it transits environmental media, and how light is affected by objects and surfaces. It also notes the spatial, spectral, and polarizational reflectances of natural scenes and of objects within these scenes. Perhaps most importantly, visual ecologists must be expert vision scientists, as the field embraces visual optics, eye and retinal design, photoreceptor diversity and function, and visual processing. And since the ultimate goal of visual ecology is to understand how visual systems of animals meet their biological needs, the ecology and behavior of species must be considered. As can be seen, the field spans levels of study from the molecules and genes of vision and visual development to the ecological niches that animals occupy, and includes most aspects of biological science as well as biochemistry, physics, and computational modeling. Including so many areas of science, visual ecology is an unusually rewarding research area within visual science.

The questions that visual ecologists ask are among the oldest in biology: "Do other animals see things the way we do?," "Do animals have color vision?," "How can some animals see underwater, or at night?," and so forth. The field itself, however, was formally recognized only after 1979, when John Lythgoe published a rather small book called *The Ecology of Vision*. Lythgoe's viewpoints have withstood the test of time unusually well, and many of the issues he raised are still very active topics in the field. I suspect that the field's founding father would be delighted to see the vitality that visual ecological research has today. In fact, in a single chapter there is simply not sufficient space to cover the state of knowledge in any detail, so the focus here is on fundamentals and on particularly interesting and promising new areas of focus in the field.

I will begin with the properties of the stimulus light, its sources, spectra, and polarizational features, as well as its distribution in natural scenes and its special roles in biology. The discussion will then proceed to animal eyes, touching on eye evolution and design, visual optics, and retinal specializations. Next, I will cover how visual function is adapted, discussing specializations for increasing sensitivity, improving spectral sensitivity and color vision, enhancing polarization vision, and managing how eye movements are controlled. The final section of the chapter will be devoted to vision's role in the lives of animals, including how it functions in animal orientation, predation and predator avoidance, and visual signaling.

1.08.2 The Visual Environment

1.08.2.1 Properties of Light

Light is, of course, a form of electromagnetic energy, but deciding what part of the electromagnetic spectrum is properly called light is rather arbitrary. The spectral region seen by humans – visible light – by convention includes wavelengths from 400 to 700 nm (though humans can see outside this range in appropriate conditions). Visual systems of other animals respond to wavelengths from near 300 nm to beyond 750 nm. The dual nature of light, possessing properties of waves and particles, is critical to recognize when considering vision. The spectral region within which photoreceptors respond arises from light's wave properties, but the actual absorption events occur photon-by-photon and are thus quantal. Another wave property of light that can be important in vision is its polarization. So a complete description of light as a visual stimulus necessarily includes its intensity (the rate at which photons arrive), its spectrum (the distribution of these photons within the visual spectrum), and its polarization (generally, the fraction of photons that have electrical vectors that are aligned parallel to a particular plane).

1.08.2.2 Intensity and Duration of Light

Animals must cope with an astonishing range of light intensities. Just on the earth's surface, the variation from full sunlight to overcast night sky exceeds 10 log units; in the sea, light is further attenuated indefinitely, depending on the depth of overlying water. Given that light absorption in photoreceptors occurs photon-by-photon, light intensities should be given in quantal units, either as irradiance or as radiance. Irradiance is the measure of the amount of light falling on a surface, typically as photons per unit time and area, and is appropriate when considering the illumination of a scene. Radiance is the amount of light arriving from a location, within a solid angle, specified as photons per unit time and area and per unit steradian. It is used when considering the distribution of light in a scene, as in a region being visually imaged. When the spectral distributions of radiance or irradiance are being considered, a spectral unit (typically per nanometer) is also necessary to specify the spectral range within which bins of quanta are summed. Full sunlight irradiance is on the order of 10^{13} to 10^{14} photons $cm^{-2}\,s^{-1}\,nm^{-1}$ at 500 nm.

Irradiance varies with the location on the earth or in its waters, and it obviously also varies with time. The primary influences on temporal light variations are astronomical and are therefore predictable. These natural variations in lighting and their influences on vision and behavior have been nicely reviewed by McFarland W. N. (1986); the biological importance of diurnal, monthly, and seasonal patterns of illumination is well known and needs little further coverage here. Higher-frequency variations in lighting, caused by atmospheric conditions, surface waves (in water), wind effects on foliage, and so on, are recognized, but their effects on vision have not yet received much research attention (McFarland, W. N. and Lowe, E. R., 1983; Loew, E. R. and McFarland, W. N., 1990; Maximov, V. V., 2000; Cronin, T. W., 2006). Changes in irradiance with location in water (including depth) and under the forest canopy are associated with far more dramatic changes in the spectral content of light and will be covered in the next section.

1.08.2.3 Spectral Properties of Natural Light

Spectral variations that occur in natural illumination (Figure 1) are nearly as challenging to visual systems as those of intensity, and a huge literature exists on the topic of visual specialization for function in different spectral environments (touched on later in this chapter). The natural spectrum changes on the surface of the earth with time of day, sky state, and location (for instance, at various places within a forest). In water, these same influences also cause spectral shifts, but the spectrum of irradiance varies more dramatically with water quality, depth, and direction of illumination.

The whitening of the normally blue spectrum of the sky under clouds is widely recognized. Less well known is that the sky overhead becomes its bluest at twilight, when sunlight is scattered by 90°; simultaneously, the light from the direction of the sun becomes its reddest as it travels to the viewer through atmospheric dust, smoke, and haze. Thus, the relatively flat spectrum of daylight sharpens into two distinct peaks (Figure 1), in the blue and red, at twilight (Rozenberg, G. V., 1966; McFarland, W. N., 1986). As this is also a time of rapidly decreasing irradiance, it is likely that animals active at this time are specifically adapted to the spectral qualities of twilight.

Terrestrial animals move or fly around. If they are in open country, the light by which they see remains essentially constant, but this is not the case for forest-dwelling species. Here, the local illumination can vary on fine spatial and temporal scales, as animals move between deep shade and brighter patches of various sizes, lit by different parts of the sky. As the intensity

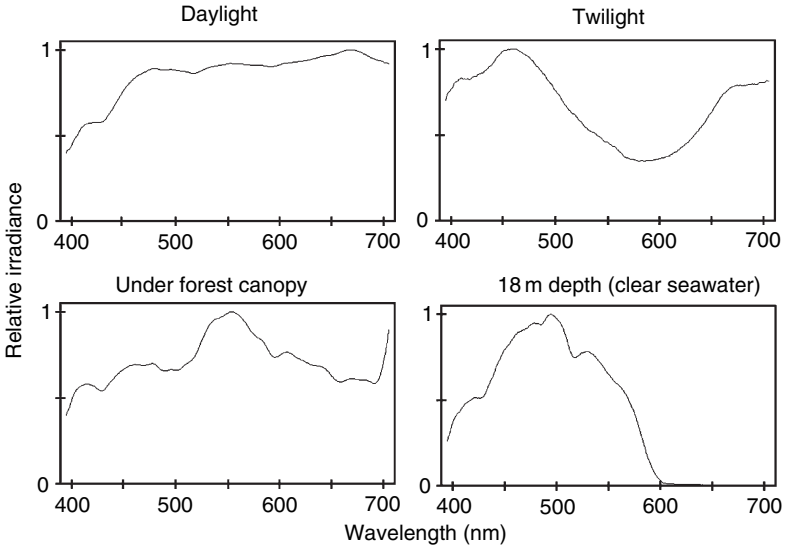

Figure 1 Typical irradiance spectra of light illuminating scenes viewed by animals, each normalized to its maximum. Top left: the daylight spectrum, which is spectrally broad and relatively flat. Top right: the spectrum at morning twilight, just at sunrise, showing the deep blue peak produced by scattering in the sky and the red peak produced by the passage of sunlight through a long atmospheric path when the sun is at the horizon. Bottom left: light in a Panamanian forest at midday, filtered by the forest canopy, showing the peak near 550 nm produced by chlorophyll in leaves. Bottom right: irradiance at 18 m depth in clear, coastal seawater, illustrating the removal of long wavelengths and the reduction in intensity at short wavelengths as light transits water.

changes, shifting contributions from direct sunlight (white), open sky (blue), and light transiting the canopy (green) produce an array of distinctive photic microenvironments (Endler, J. A., 1993; Chiao, C.-C. *et al*., 2000a). Animals can use such places for particular tasks depending on their appearance in them.

Underwater, the lighting situation is even more variable. There are still the diurnal variations in spectrum just described, at least near the surface, and lighting varies under aquatic vegetation much as it does in the forest (Cummings, M. E. and Partridge, J. C, 2001). Changes in spectral content produced by the water itself, however, probably have the greatest impact on aquatic species (reviews: Jerlov, N. G., 1976; Lythgoe, J. N., 1988; Loew, E. R. and McFarland, W. N., 1990). Water is a spectral filter, preferentially transmitting light near 475 nm, and the dissolved and suspended matter in natural waters increases the absorption of light and shifts its spectral distribution by up to 100 nm (or occasionally more) to longer wavelengths. Species that live in estuaries or other varying waters, that migrate between water types, or that change habitats with development, must cope with these variations. The filtering effects of water become increasingly critical at greater depths. Even in the clearest oceanic waters, which transmit light nearly as well as pure water does, light becomes dim and virtually monochromatic within a few hundred meters (Tyler, J. E. and Smith, R. C., 1970).

The relatively simple and predictable photic properties of water, particularly regarding the distribution of radiance and the transmitted spectrum, make it an ideal natural laboratory for investigations of visual design and function. Light is filtered as it enters water and again after it reflects from an object, and new light is scattered into the visual path, creating a unique, low-contrast, but optically well-defined visual environment (Figure 2). Much of the theory within visual ecology has been developed using aquatic systems and species, and the aquatic environment remains important for hypothesis generation and testing.

Figure 2 Reduction in color range and image contrast underwater produced by light absorption, background scattering, and veiling radiance. The upper photograph was taken of a school of squid, seen from a distance of about 3 m and at a depth of about 1 m in clear seawater. Note that scattering and absorption of light, even at this very shallow depth and relatively short viewing distance, produce a greenish-blue cast to the entire image and almost completely obscure both the squid and the coral beneath them. Color and brightness contrast were restored in the lower image to reproduce the approximate appearance of the scene to the photographer (the author) when the image was captured.

1.08.2.4 Polarized Light in Nature

The light produced by natural sources is weakly polarized at best, but polarized light is nevertheless abundant in nature (reviews: Waterman, T. H., 1981; 1984; Wehner, R., 2001). In the sky and underwater, scattering of incoming light produces partial linear polarization that varies with solar position and direction of view. Reflection of light from the air–water interface or from shiny surfaces (e.g., leaves, wet surfaces, animal skin, scales, or cuticle) also produces strong polarization in geometrically favorable circumstances. Terrestrial animals that detect polarized light, like insects, can use the reliable polarization patterns of the sky for navigation. On the other hand, for such animals, the chaotic and unpredictable pattern of polarized-light reflection can mask or taint the true colors of objects. Animals with polarization vision often employ special adaptations that eliminate polarization sensitivity in some spectral receptor classes to retain a form of color constancy (Wehner, R. and Bernard, G. D., 1993; Marshall, N. J. *et al*., 1999), or they may evaluate viewed objects using combined spectral and polarizational cues (Kelber, A., 2000;

Kelber, A. *et al.*, 2001). Light reflected from the surface of water presents a very strong polarization cue for many flying insects (Schwind, R., 1984; Schwind, R., 1991; Horváth, G. *et al.*, 1997).

The best-studied celestial polarization patterns are produced by scattered sunlight, and similar distributions of polarized light that appear in the sky when the moon is bright are useful to some nocturnal insects (see Gál, J. *et al.*, 2001; Dacke, M. *et al.*, 2003; 2004). Skylight polarization is exceptionally strong and stable at twilight (Figure 3), for about an hour before dawn and after sunset (Cronin, T. W. *et al.*, 2006). The polarization pattern of the twilight sky could be important for orienting both insects (Greiner, B. *et al.*, 2004) and vertebrates (Helbig, A. J., 1990).

Terrestrial scenes provide complex and shifting patterns of celestial polarization and reflections of polarized light from shiny objects, but the situation is almost always simpler underwater. Due to refraction at the air–water interface, illumination from the sky is within 46° of overhead at all times. The resulting light field is nearly horizontally polarized most of the time (Waterman, T. H, 1981; Cronin, T. W. and Shashar, N., 2001). Polarization under water is generally weaker than in the sky, and little polarization is produced by reflection from objects, as the refractive index gradient between water and most objects is less than in air. Despite this, polarization vision is common in aquatic animals, for reasons to be discussed later.

1.08.2.5 Natural Scenes

Natural scenes have special properties, quite different from those of either purely random or highly ordered geometric arrays. The relationships between the properties of natural scenes and the sensory systems are central to understanding sensory ecology. All natural stimuli exist within extended scenes (most obviously for visual, auditory, and chemical stimuli), and it is evident that environmental features of stimuli constrain the evolution of sensory systems (see Wehner, R., 1987). Understanding how spatial, temporal, and spectral properties of visual systems, as well as features of biological signaling, are molded by natural scenes requires appropriate descriptions of these scenes.

Natural visual scenes are scale invariant (Ruderman, D. L., 1994); their spatial properties are the same at any magnification. This result probably emerges from the presence of self-similar objects (e.g., trees, grass, and rocks) at all viewing distances and thus at all spatial scales (see Burton, G. J. and Moorhead, I. R., 1987; Ruderman, D. L. and Bialek, W., 1994). Common properties of visual systems, including sparse coding (Olshausen, B. A. and Field, D. J., 1996), lateral inhibition (Srinivasan, M. V. *et al.*, 1982; Laughlin, S. B., 1994), predictive coding (Srinivasan, M. V. *et al.*, 1982; Attick, J. J., 1992; Hosoya, T. *et al.*, 2005), and spatiotemporal processing (van Hateren, J. H., 1992; Laughlin, S. B. and Weckstrom, M., 1993; van Hateren, J. H., 1993), can be explained by natural scene properties. Later in the chapter, I will consider how scene spectral features have influenced the evolution of color vision. Current work on natural scenes includes research on how animals integrate themselves into these scenes for signaling and concealment.

1.08.2.6 The Biological Visual Environment

Even the simplest visual task must cope with many of the aspects of light and the visual environment

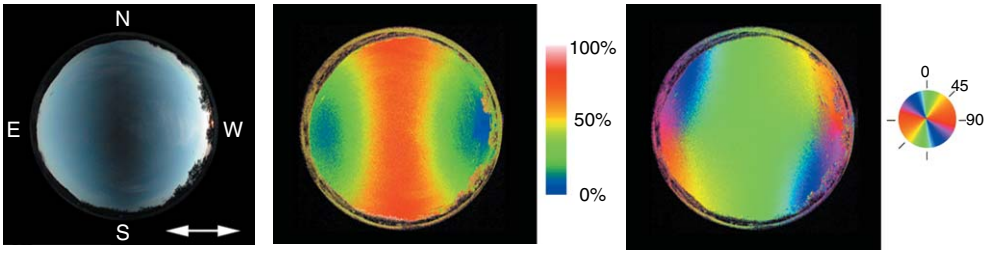

Figure 3 Polarization images of the clear sky at sunset near the autumnal equinox. All panels show the same celestial pattern. The left panel illustrates the appearance of the sky seen through a polarizer oriented E/W, and shows the strong N/S-oriented polarization as a dark band extending directly across the zenith. The middle panel is a false-color image illustrating the degree of polarization (% polarization), coded as in the key to the right. Note how strongly the N/S polarization band is polarized (~80%), with polarization falling in a symmetrical pattern toward the east and west. The right panel shows the *e*-vector angle (polarization angle) at each point in the sky, coded as illustrated in the key to the right. Again, note the extremely symmetrical pattern of polarization, with polarization in the N/S band all oriented parallel at about 0°.

presented above. This demands a lot from a visual system, as engineers have learned when designing even basic, artificial visual devices. Vision's evolution is influenced by the features of the physical and natural environment, but its function is biological. Thus, animals that inhabit similar habitats, even those active under very similar circumstances, require their visual systems to perform quite specific tasks, and similar animals often have different visual needs. Predators must track down their prey, while the prey strive to detect predators first. Bees and hummingbirds fly to flowers, but fruit bats and primates search trees for fruit. Navigating desert ants must find their way home in a featureless world, while forest ants have a superabundant set of visual cues to use to orient. Octopuses vary their appearance to disappear against backgrounds, while poisonous seaslugs in the same spot appear maximally conspicuous. Vision is involved in all these situations, and the huge diversity of visual systems and visual tasks motivate visual ecologists to attempt to understand how it all works.

1.08.3 Visual Systems and Visual Evolution as Related to Visual Ecology

1.08.3.1 Eye Design and Its Variation

Even a single photoreceptor cell provides useful information about the time of day or the passage of shadows, but complex eyes are needed if an animal requires far more than this. All eyes have two sets of functional components: a retina containing an array of photoreceptors that provide input into some sort of central or higher-order processor (or at least an effector) and a dioptric apparatus that controls how light reaches the retina by refraction, reflection, and/or absorption.

Eyes have apparently evolved independently a number of times, although it does seem possible that all eyes in existence today trace back to as few as two ancestral organs or cell masses (Oakley, T. H. and Cunningham, C. W., 2002; Nilsson, D.-E., 2005). There are about nine fundamentally different optical designs in modern eyes (Land, M. F., 1981; Land, M. F. and Nilsson, D.-E., 2002; Land, M. F., 2005;), divided into two main groups, simple (or single chambered) and compound. However, operating principles of eyes can be so divergent that it is often difficult to see how one type evolutionarily relates to another. Visual ecologists tend to not be so concerned with the evolutionary pathways that link eyes as with the evolutionary specializations that shape them for particular functions.

1.08.3.2 Visual Optics

The simplest eyes can hardly be said to have optics at all. Pigment-cup eyes consist of an invaginated retina backed by a layer of pigment, but they still provide a low-resolution representation of the outer world on the retina: objects to the left map to regions on the right side of the retina, and so forth. Though insensitive and incapable of much acuity, pigment-cup eyes give a basic sense of light's direction and change, and can mediate orientation or defensive behavior (Nordström, K. *et al.*, 2003; Land, M. F., 2003). Groups of pigment cups – perhaps the ancestors of today's highly evolved compound eyes – serve as detectors of approaching or passing objects (Nilsson, D.-E., 1994).

It is a surprisingly short distance from a pigment-cup eye to an optically excellent lens eye. Nilsson, D.-E. and Pelger, S. (1994) estimate that evolution could shape the change in less than a half-million years, even assuming quite weak selection. Good eyes based on spherical refracting lenses require a properly shaped gradient of refractive index from the center to the margin of the sphere (Land, M. F., 1981; 2005), but such eyes have turned up repeatedly, in quite disparate taxa. An unexpected example of this occurs in box jellyfish, animals that lack a central nervous system but nevertheless have eight optically excellent lens eyes of two types (Nilsson, D.-E. *et al.*, 2005). Strangely, even though each lens in these jellyfish eyes forms a sharp image, in life the retina is much closer to the lens than the focal plane. This produces severely underfocused images on the retina, perhaps suitable for sensing the overall light field while blurring out the shapes of small, floating objects.

Most animals with quality lens eyes, ranging from worms to octopuses to vertebrates, put the retina where it belongs, at the lens's plane of focus. These eyes all operate on the same fundamental optical principle, refracting light using spherical surfaces to produce the image. The most important differences among lens eyes relate to the medium in which they are used. The sudden change in refractive index when light enters ocular media from air means that in aerial vision the cornea, the outermost optical structure in a lens eye, normally has most of the refractive power used to form the image. In water, however, there is only a slight change in refractive index between water and the cornea, so the spherical lens, with its radial

refractive index gradient, is the major image-forming element. Eyes of amphibious animals must have special adaptations for effective use in both media; the functioning of amphibious lens eyes has been reviewed by Sivak J. G. (1988); see also the classic work on vertebrate eyes by Walls G. L. (1942), as well as Land M. F. and Nilsson D.-E. (2002).

The lens eyes of some deep-sea fishes show a particularly elegant functional modification. Due to refraction at the water's surface and further absorption as light travels down through the water column, sunlight in the deep sea is confined to an overhead patch perhaps 90° across. Predatory fishes look up into this window of light, searching for prey silhouetted against it and maximizing visual contrast by gathering as much light as possible. For optimal viewing in this limited visual field, they have discarded all but the central region of the retina; the resulting bullet-shaped eye is called a tubular eye (Warrant, E. J. *et al.*, 2003; Warrant, E. J., 2004; Figure 4). Despite its odd appearance, the tubular eye is functionally identical to any other fish eye;

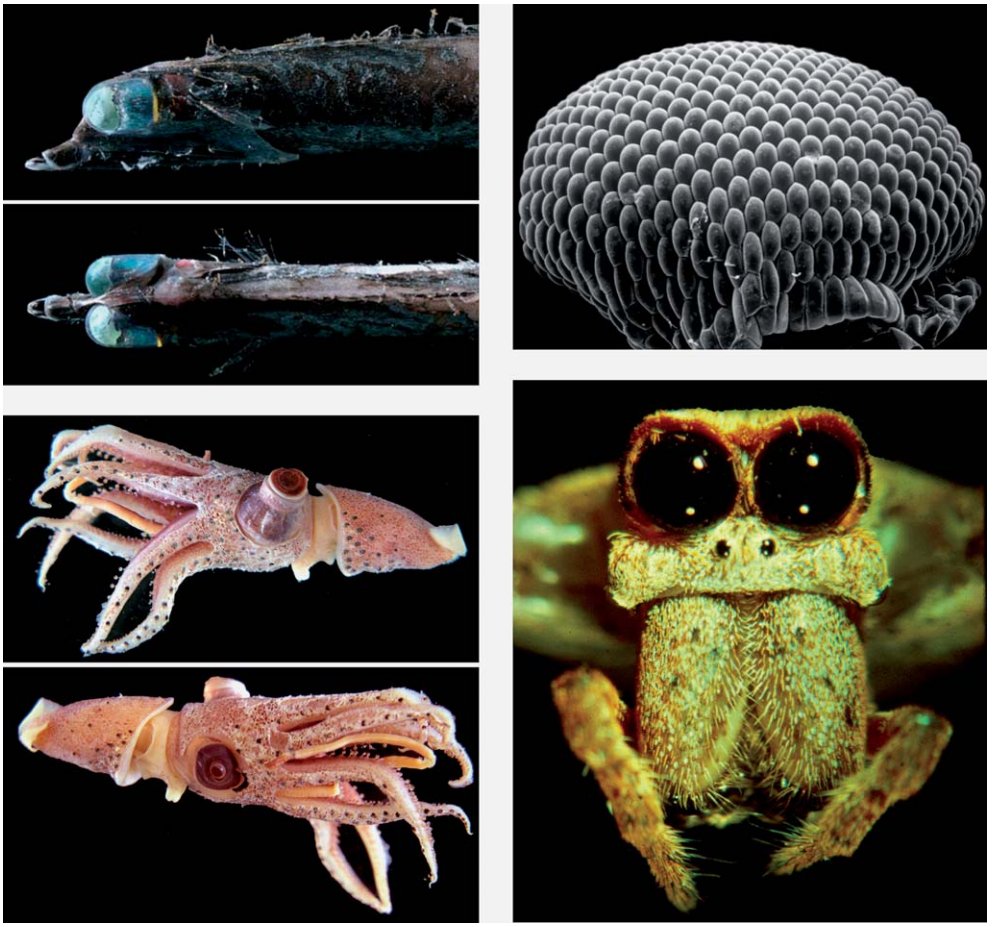

Figure 4 Eyes designed for visual function in conditions of very limited light. The left top panel pair shows the tubular eyes of the deep-sea fish *Stylephorus chordatus* in lateral and dorsal view. Photograph courtesy of E. A. Widder. Notice how the bullet-shaped tubular eyes face forward on the body axis, suggesting that the fish hunts while hanging vertically in the water. The lower panels show the asymmetrical eyes of the deep-sea squid *Histioteuthis* sp. The squid's right eye is also a tubular eye, functioning optically like that of *S. chordatus*, while the left eye is of normal size and has an extended visual field. The squid presumably hunts while swimming on its side, with the tubular eye directed upward (photographs by the author). The top panel on the right side shows the tubular compound eye of a euphausiid crustacean (probably *Nematoscelis*). The dorsal half of this eye, shown, has its ommatidia arranged to sample the same limited downwelling light field as seen by the tubular lens eyes of *S. chordatus* and *Histioteuthis*, revealing convergent optical design. The ventral half of each divided eye, not shown, is expanded to form a hemispheric field of view. Photograph courtesy of D. Pales. The lower right panel illustrates the lens eye of the spider *Dinopis subrufus*, which has an *F*-number of 0.6 (the lowest known for any lens eye), used for nocturnal hunting. Photograph courtesy of M. F. Land.

the only difference is that there is no retina present outside the central viewing area. Tubular eyes and their analogues also exist in a number of invertebrate deep-sea species (Figure 4).

Lens eyes have traditionally been likened to photographic cameras because their operating principles are so similar. Visual optics of other eye types are so diverse – and unfamiliar – that there is insufficient space in a review of this nature to describe them adequately. The best references to consult for more information are Land's and Nilsson's book, *Animal Eyes* (2002), and also Land's 1981 and 2005 reviews.

Compound eyes use a diverse and astonishingly complex assortment of optical principles to form images (Nilsson, D.-E., 1989), but these eyes are all built of an array of numerous, similar elements that sample space in a neatly geometrical pattern. With minor exceptions, they function analogously to other eye types, using a matrix of photoreceptor elements that correspond to points in visual space. It is convenient, therefore, to think of the receptor array as a retina and to consider how space is sampled as one would for any other retina, discussed in the next section.

1.08.3.3 Receptor Arrays and Retinas

As just suggested, retinas are generally made up of a geometrical array of photoreceptors that correspond to a similar array of spatial locations. The overlying optical elements govern how much light reaches each receptor and set a limit to visual resolution. While sensitivity and resolution are fairly constant across the retina in most eyes, they can vary considerably among receptors in some compound eye types. The visual ecological significance of retinal design arises from this sensory mapping of the external world. In a quite literal sense, retinal design informs us about the concerns and expectations of a species (see Wehner, R., 1987).

Few eyes sample visual space evenly, and those that do are generally simple in design or of very limited optical quality. Complex, image-forming eyes instead tend to use a disproportionate number of receptors to sample a relatively small portion of the whole visual field, so that it can be seen in extraordinary detail. The extended retinas of simple eyes normally control spatial sampling by varying the amount of neural convergence from receptors onto the neural elements that lead to the central nervous system (retinal ganglion cells in vertebrate eyes). A region of dense sampling often forms a depression in the retinal surface, and is therefore called a fovea (meaning pit). Compound eyes fine-tune sampling using variations in the angular spacing among adjacent units (each unit of a compound eye is called an ommatidium). When ommatidia are arranged so that the angular separation between neighbors is unusually small, this produces a region of elevated resolution termed an acute zone. Since acute zones of compound eyes are functionally equivalent to foveas of simple eyes, the term fovea is often generally used to designate any ocular region of high visual acuity (Figure 5).

In a given eye, the fovea might map to a single spot in the outside world, a common situation in animals with binocular vision. Or it might correspond to an extended location, such as the horizon; this is frequently seen in prey animals, especially in those that inhabit flat spaces such as plains or sand flats (reviewed in Cronin, T. W., 2005). Many species have multiple foveas in a single eye; for instance, vertebrates whose eyes face to the side almost always have one fovea sampling space in front of the head and another aimed laterally (Figure 5). The quality of vision in each fovea can vary according to the animal's needs. An interesting example is seen in raptors, aerial predators, where the extremely acute lateral fovea is used to detect and track prey. Since this part of the eye actually faces 45° to the flight path, the hunter spirals in as it attacks prey (Tucker, V. A., 2000). Invertebrate raptors, dragonflies, provide interesting analogues to this. Their compound eyes have a relatively weak acute zone aimed ahead plus a large, laterally extended one sampling the sky above and slightly in front of the direction of flight (Sherk, T. E., 1978). This permits them to image small flying prey against the bright sky background and to attack them with an upwardly swerving flight, while remaining relatively invisible below the intended prey, out of its best field of view.

Foveas in lens eyes by definition have little neural summation, and often contain unusually narrow, tightly packed photoreceptors. Thus, they are normally less sensitive to light than other retinal regions (this is why the most sensitive vision in humans is in the peripheral field). Acute zones of compound eyes, on the other hand, can combine sensitivity with acuity. In fact, in compound eye design these properties are linked because diffraction in the tiny corneal lenses limits spatial resolution (reviews: Snyder, A. W., 1979; Land, M. F., 1981). As neighboring ommatidial axes become more parallel, paradoxically the corneal facets must become larger to provide adequate resolution. This tends to flatten the surface of the compound eye and provides both improved acuity

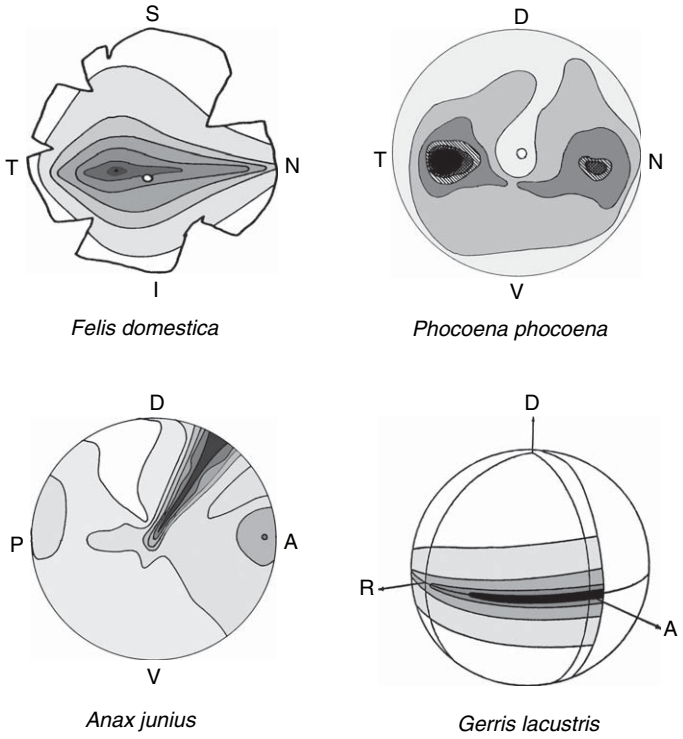

Figure 5 Sampling of the visual field by right eyes of vertebrates (top panels) and arthropods (bottom panels). Increasing density of fill indicates regions of increased acuity, sampled either by greater densities of ganglion cells in vertebrate retinas or by more tightly packed ommatidial arrays in compound eyes, but the coding does not indicate identical acuity values in the different panels. White circles near the centers of the vertebrate retinas show the location of the optic disk, where axons of retinal ganglion cells enter the optic nerve. Top left: The house cat, *Felis domestica* (after Land, M. F. and Nilsson, D.-E., 2002), illustrating the single central fovea and a suggestion of a horizontal visual band, or visual streak. Top right: Harbor porpoise *Phocoena phocoena* (after Mass, A. M. *et al.*, 1986), showing the two foveas, one directed forward and the other laterally. *Bottom left*: dragonfly *Anax junius* (after Sherk, T. E., 1978) to show the strip-shaped band of high acuity facing upward and forward, with a second smaller anterior acute zone. Bottom right: Visual fields of the waterstrider *Gerris lacustris* (after Land, M.F. and Nilsson, D.-E., 2002 using data from Dahmen, H., 1991). Note the extensive horizontal acute zone, representing the visual streak that samples the flat surface of the water on which *G. lacustris* lives. S, superior; I, inferior; T, temporal; N, nasal; D, dorsal; V, ventral; R, right. Reproduced from Cronin, T. W. 2005. The Visual Ecology of Predator-Prey Interactions. In: Ecology of Predator-Prey Interactions (*eds.* P. Barbosa and I. Castellanos), pp. 105–138. Oxford University Press, with permission.

and sensitivity at once. So the acute zone of a compound eye can have elevated sensitivity at no cost in resolution. For example, eyes of male blowflies, *Chrysomyia megacephala*, are specialized as dot detectors, having a very sensitive region looking overhead for the tiny silhouettes of female flies (van Hateren, J. H. *et al.*, 1989). Compound eyes also produce analogues of the horizontally extended foveas in eyes of vertebrates that live in flat terrain (see Walls, G. L., 1942). Fiddler crabs, denizens of sand flats, and waterstriders, who inhabit the flat surfaces of ponds and streams, both have compound eyes with acute zones that extend horizontally around the eye (Zeil, J. *et al.*, 1986; 1989; Dahmen, H., 1991). Their eyes are beautifully designed to pick out objects sitting on the level planes of their worlds (Figure 5).

The final word in this section is reserved for spiders, many of which have visual systems that combine features of both lens and compound eyes. Most spiders have eight lens eyes, aimed to cover the visual field with areas of both low and high resolution. Not only does this give excellent spatial coverage, but it also breaks up the world into different functional zones, some of which are monitored for suspicious events (like moving objects) while others are viewed in fine detail (Duelli, P., 1978; Land, M. F., 1985a; 1985b). Wolf spiders (Lycosidae) and jumping spiders (Salticidae), creatures that stalk their prey or make visually directed ambushes, have the highest-resolution vision of any terrestrial invertebrate (Land, M. F., 1985a), permitting unusually complex hunting and mating behavior.

1.08.4 Visual Function as Related to Visual Ecology

1.08.4.1 Visual Sensitivity (Brightness Adaptation)

Animals that use their eyes on the earth's surface during the day are provided with a wealth of photons for seeing, as something like 10^6 photons reach each photoreceptor per second (Land, M. F. and Nilsson, D.-E., 2002). This number is more than adequate for standard visual tasks, but still, only 1000 or so quanta arrive per millisecond, which limits signal quality in very fast-responding receptors. Human vision becomes barely possible on overcast, moonless nights, when the intensity is reduced by 10 orders of magnitude, providing the average receptor with a photon once every 10 000 s. Yet, under these conditions, and even more challenging ones in the deep sea, some animals see very well. How their visual systems achieve the required sensitivity is a classic question in visual ecology.

Vision starts with the photoconversion of a molecule of visual pigment, followed by the transduction of this event to initiate a neural signal. A single photon is sufficient to produce a usable change in photoreceptor membrane potential, but at this threshold vision is ruled by statistics. Not all photons are absorbed by visual pigments, not all absorptions activate the pigment, and not all activations lead to phototransduction. Furthermore, visual pigments can be activated in the dark by random thermal events; while these occurrences are rare, they become critically important near vision's threshold. Also, the photoreceptors must be fed with light, so light must enter and transit the optics of the eye, be properly collected and focused on the retina, and pass into the photoreceptor. Losses occur at every stage of this sequence. And ultimately, vision is a process that requires statistically distinct differences between photoreceptor signals both in time and in space, not just on catching the odd photon. Considering all that is required, it sometimes seems a wonder that animals see at all.

A photoreceptor's sensitivity to an extended scene increases with the area of the collecting aperture, the inverse of the focal length of the optics, the diameter and length of the receptor, and the density of visual pigment in the receptor (Land, M. F., 1981; Warrant, E. J. and Nilsson, D.-E., 1998; Warrant, E. J., 2004). Photopigment density is fairly consistent within phylogenetic taxa, with absorption ranging from 1% μm^{-1} to 3% μm^{-1} of receptor length. Animals can therefore increase sensitivity by increasing photoreceptor length and diameter and by making large eyes with big apertures but short focal lengths. Of course, all these adaptations have costs, and almost every improvement means that an animal must carry around and operate a bigger chunk of optical machinery.

Taking the *F*-number (aperture divided by focal length) of an eye is a simple way to estimate the image brightness on the retina – the smaller the *F*-number, the brighter the image. The dark-adapted human eye has a pupil diameter of about 8 mm and a focal length of 17 mm, giving an *F*-number near 2.1. Other vertebrate lens eyes reach minimal *F*-numbers near 1.25 in many fishes (see Land, M. F. and Nilsson, D.-E., 2002; Warrant, E. J. *et al.*, 2003) and similar or even lower values in nocturnal birds (Martin, G. R. *et al.*, 2004; Warrant, E. J., 2004). The minimum known *F*-number for a lens eye is 0.6, found in a nocturnal spider, *Dinopis subrufus* (Figure 4), and the best *F*-number of all, 0.25, is produced by the mirror eyes of a deep-sea ostracod (Land, M. F., 1981; Warrant, E. J., 2004). Interestingly, these record-breaking eyes are all extremely small and have relatively few photoreceptors, so their optical quality need not be perfect. Low *F*-numbers mean a bright retinal image, but there is a cost for vision in addition to the possible reduction in optical quality – the angular extent of the cone of light illuminating each receptor is broad, so light could fail to be trapped in the central receptor and even pass laterally between receptors.

Increasing photoreceptor diameter provides a larger area for light capture, but reduces the number of sampling points on the retina as a whole. On the other hand, photoreceptor length increases have little effect on spatial resolution. Another adaptation is to place a mirror layer, or tapetum, behind the neural retina to reflect transmitted light back through the receptor layer for a second chance at absorption. Tapetal layers are very common in nocturnal eyes of vertebrates (Walls, G. L., 1942), giving them their famous eyeshine. Among invertebrates, they occur in nocturnal spiders (Land, M. F., 1985a) and in the compound eyes of butterflies, moths, and marine crustaceans (Land, M. F., 1981). Another solution that effectively increases retinal thickness (if not receptor length) is to place photoreceptors in multiple layers. This is seen in many deep-sea fishes (Warrant, E. J. *et al.*, 2003; Warrant, E. J., 2004) and has recently been discovered in a nocturnal bird species, the oilbird *Steatornis caripensis* (Martin, G. R. *et al.*, 2004).

A final way to get more photons into photoreceptors is to decrease their reflective loss at the cornea. Compound eyes of many terrestrial arthropods use photonic solutions to enhance corneal transmission, covering each corneal facet with a lawn of tiny bumps termed corneal nipples by their discoverers (see Miller, W. H., 1979). These mimic the effect of a smooth transition in refractive index moving from air into the corneal matrix, increasing transmission while minimizing glare. Reflection suppression by corneal gratings has even been found in an extinct fly species (Parker, A. R. *et al.*, 1998).

The adaptations discussed so far are anatomical. Some are kludged together to make an optically limited eye of low resolution but with adequate sensitivity to meet the requirements of a small animal that must survive at night or in very dark water. Others are elegant fine tunings of optically outstanding ancestral eyes, as in deep-sea fishes or oilbirds. Ultimately, however, anatomical modifications reach their limits, and evolution then has only two ways out if a species must function in a darker world. The eye can increase in size, thereby providing a larger retina to hold bigger photoreceptors, or the visual system must turn to physiological solutions that improve sensitivity, using neural tactics to enhance vision that has reached terminal optical constraints (see Snyder, A. W. *et al.*, 1977; Laughlin, S. B., 1981; Warrant, E. J., 2004). Signals from individual receptors can be summed over time (effectively increasing integration time, thereby reducing temporal resolution), a process called temporal summation. Or the inputs from a number of adjacent receptors can be combined into a single neural signal (increasing collection area, reducing spatial acuity), termed spatial summation. Of course, spatial and temporal summation are commonly employed in unison, producing some appropriate compromise of decreased temporal or spatial acuity.

Integration times of photoreceptors often are adaptive for the ecological characteristics of species, as discussed earlier (see Laughlin, S. B. and Weckström, M., 1993), and they are commonly adjusted in individual receptor cells during the process of light or dark adaptation. It is also possible that higher-order neurons may accumulate photon signals over time, further increasing summation times (see Warrant, E. J. *et al.*, 1996). In some eyes, particularly compound eyes, individual photoreceptors alter their receptive field sizes during adaptation (e.g., Barlow, R. B., Jr. *et al.*, 1988). However, it is most common for receptors to be combined neurally, converging onto a single postsynaptic cell. Such cells extend horizontally in the retina, collecting inputs from a number of photoreceptors. An excellent example of this exists in the nocturnal bee, *Megalopta genalis*. Unlike almost all other bees, this unusual species flies under the rainforest canopy at twilight, well before sunrise or after sunset. It is capable of orienting itself in light intensities where human vision is impossible, and does this using a compound eye that is fundamentally the same as those of day-flying insects like honeybees. The immense increase in sensitivity required for this task is partially accomplished by extensive spatial summation, thought to be enabled by widely branched neurons onto which photoreceptors synapse (Warrant, E. J. *et al.*, 2004; Greiner, B. *et al.*, 2005). Theoretical analysis of summation suggests that visual function is surprisingly well maintained both spatially and temporally, even when sensitivity is improved by many orders of magnitude (Theobald, J. C. *et al.*, 2006). Some night-flying insects, for instance the hawkmoth, *Deilephila elpenor*, even maintain color vision in starlight intensities through the use of neural summation (Kelber, A. *et al.*, 2002).

1.08.4.2 Spectral Sensitivity, Color Vision, and Ultraviolet Vision

How the spectral sensitivities of photoreceptors should be tuned for best visual function is one of the oldest questions in visual ecology. If a photoreceptor is needed solely to catch available photons, then it seems obvious that its spectral sensitivity should somehow match the available spectrum of light (although, as will be seen shortly, even this may not be optimal). But vision is more than simple photon capture. It involves detecting the variations in light throughout a scene and sorting out the differences in light arriving from significant as opposed to insignificant sources (typically, objects vs. backgrounds). Thus, the fundamental requirement of a visual system is contrast detection. When the photic environment is nearly monochromatic (as in the deep sea), and everything is seen in a single spectral region, optimization of vision for sensitivity is equivalent to optimization for contrast. Most visual environments are far more spectrally complex (and often quite variable), and it is not often simple to predict how visual photoreceptors should be spectrally fit to visual tasks.

Photoreceptor spectral sensitivity is primarily determined by the spectral absorbance of the visual pigment it contains; typically, a single visual pigment class dominates in a given receptor class. All visual

pigments are derived from an opsin, a G-protein-coupled receptor protein, combined with a chromophore (either a retinaldehyde or a closely related derivative). Spectral tuning of the visual pigment results from interactions between charged amino acids in the chromophore-binding pocket of the opsin and the chromophore itself. Depending on opsin sequence, the wavelength of maximum absorption (λ_{max}) can range from near 300 nm, in the deep ultraviolet (UV), to beyond 600 nm, well into the red. There is also a chromophore-specific effect on λ_{max}: visual pigments that use 3,4-dehydroretinal as a chromophore (often termed A2 visual pigments) absorb at distinctly longer wavelengths than those with identical opsins bound to retinal itself (A1 visual pigments). Nevertheless, within each chromophore type the absorbance spectrum of the visual pigment is fully predictable, given the λ_{max} (Dartnall, H. J. A., 1953; Lipetz, L. E., and Cronin, T. W., 1988; Stavenga, D. G. *et al.*, 1993). This mathematical property makes it easy to model the potential performance of various visual pigments in any specified spectral environment, which has stimulated much recent work on the design of spectral sensitivity systems and the evolution of visual pigments and photoreceptors. The close and causally direct link between protein sequence, visual pigment absorbance, and (potentially) evolutionary history and current function make studies of visual ecology particularly attractive to sensory ecologists and evolutionary biologists.

The simplest spectral environments exist in the sea. Light near the surface has a broad spectrum, like light in the terrestrial world, but as depth increases the spectrum narrows rapidly, producing an asymptotic transmitted waveband that varies with water type and quality (Jerlov, N. G., 1976; Lythgoe, J. N., 1979; 1988). Modeling visual function in these simple spectral worlds is straightforward and generally successful in explaining the major visual pigment class of midwater and deep-sea animals (Lythgoe, J. N., 1972; Forward, R. B., Jr. *et al.*, 1988; Partridge, J. C., 1990; Marshall, N. J. *et al.*, 2003). The models predict that in seawater, the visual pigment maximum will move to shorter wavelengths as depth increases. Thus freshwater, amphibious, and shallow-water species have rod pigments that absorb maximally near or beyond 500 nm, and pigment λ_{max} decreases as the preferred foraging depth increases. This result even applies to animals like marine mammals, which commute to and from the surface to breathe (or, in the cases of pinnipeds, haul out onto beaches from time to time); their scotopic (dim light) photoreceptors are evidently adapted for best vision at the depth where each species searches for food (Fasick, J. I. and Robinson, P. R., 2000; Levenson, D. H. *et al.*, 2006).

Many species of animals that live in fresh water utilize the substantial spectral shifts available by changing chromophores on a single opsin. For example, exchanging retinal for 3,4-dehydroretinal shifts λ_{max} from 533 to 567 nm in crayfish (Zeiger, J. and Goldsmith, T. H., 1989). The use of A2 pigments should be favored in the relatively longer-wavelength freshwater (and even coastal marine) environments, which probably accounts for the presence of A2 types in many mysid (shrimplike crustaceans) species (Jokela-Määttä, M. *et al.*, 2005). In crayfish, and also many species of cold-blooded vertebrates inhabiting freshwater, changes of the chromophore occur seasonally, with the use of 3,4-dehydroretinal peaking in the winter (Bridges, C. D. B, 1972; Knowles, A. and Dartnall, H. J. A., 1977; Tsin, A. T. C. and Beatty, D. D., 1979; Suzuki, T. *et al.*, 1984; 1985). Since the use of A2 pigments is clearly appropriate in freshwater environments, the seasonality of the change between A1 and A2 visual pigments is interesting. A likely explanation is that the long-wavelength-absorbing forms are relatively unstable when warm and therefore are usable only in cold, wintry water (see Temple, S. E. *et al.*, 2006). This idea will be explored further later on.

While a ready explanation exists for the spectral positioning of visual pigments in many aquatic animals (especially those of low-light, or scotopic, receptor types), there is no simple way to account for the scotopic visual pigments of terrestrial species. Modeling invariably finds that in daylight, photon capture increases monotonically with visual pigment λ_{max} through at least 600 nm (Figure 6; see also Forward, R. B., Jr. *et al.*, 1988), suggesting that optimal visual pigments should have their maximum at 600 nm or even longer. But rod pigments of terrestrial vertebrates rarely peak beyond 500–505 nm, and the most sensitive receptors of terrestrial invertebrates have λ_{max} near 540 nm or less. The disparity between the predicted and the actual spectral locations is possibly explained by increasing thermal instability with greater λ_{max}. Activation energies of visual pigments decrease as λ_{max} increases, leading to rising levels of dark noise (Ala-Laurila, P. *et al.*, 2004). Given the immense number of visual pigment molecules in each photoreceptor cell, even very low rates of spontaneous activation mask the signals produced by rare photons near threshold. In fact, at low body temperatures, vertebrates like amphibians have

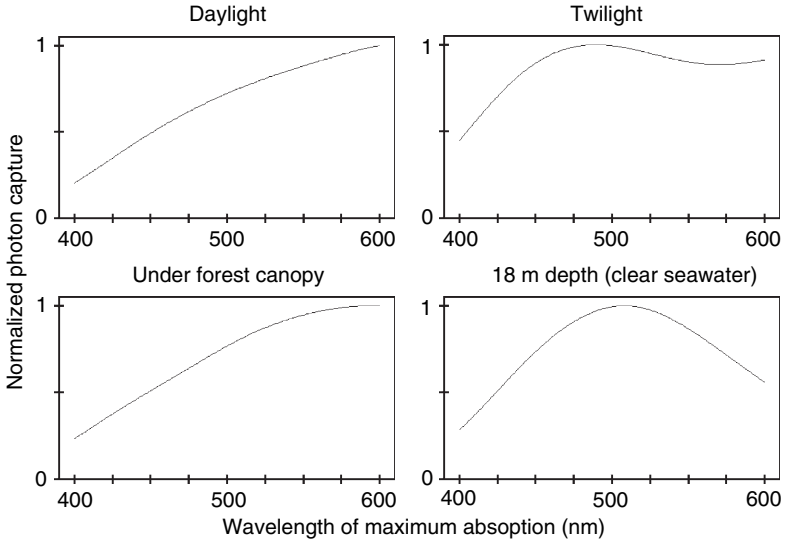

Figure 6 Relationship between photon capture and visual pigment λ_{max}, using template spectra developed by Stavenga D. G. *et al.* (1993) and assuming a total visual pigment absorbance of 0.75 in the photoreceptor. The modeling was done using the irradiance spectra portrayed in Figure 1, with panels arranged in the same arrangement. Note that generally photon capture increases with visual pigment maximum, with a small secondary maximum near 500 nm under the strongly spectrally biased illumination of twilight. The only exception is at depth in seawater, where the most effective visual pigment has its λ_{max} placed near the irradiance maximum due to the very narrow irradiance spectrum there.

significantly lower thresholds for light detection than do humans, a result of reduced random thermal isomerization of visual pigments in rods (Aho, A.-C. *et al.*, 1988). So the presence in dim-light receptors of visual pigments absorbing at unexpectedly short wavelengths likely results from the requirement to limit dark noise.

Only a few species of animals have just one photoreceptor class, and vertebrates are unusual in reserving a photoreceptor set (the rods) for use only in dim light. Besides their rods, nearly all vertebrate species possess at least two cone classes (Figure 7), and the huge majority of the invertebrates that have been studied have two or more spectral photoreceptor types. Figure 8 displays an assortment of color receptor sets, all from animals that are active in the daytime in brightly lit environments and that have been demonstrated to have true color vision. The diversity of both the number of spectral classes and the spectral placements of receptors is very impressive (and mildly disturbing).

The spectral positioning of receptor types in dichromatic color-vision systems (those with two color receptor classes) is well studied, and in many cases the design of these systems can be satisfactorily explained. Color vision is defined as the ability to discriminate among stimuli on the basis of their hue, independently of any other stimulus property (such as brightness or polarization). Thus, the ability to discriminate is fundamental to color vision, so modeling of dichromatic systems has generally proceeded on the assumption that

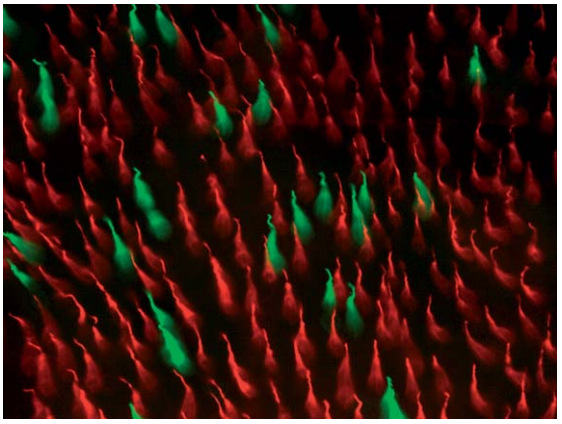

Figure 7 A region of the ventral retina of the chinchilla, showing the presence of two cone classes. Medium-wavelength absorbing cones are labeled with an antibody treatment that fluoresces red, while short-wavelength-absorbing cones are labeled with a green-fluorescing antibody. As in most mammals, only two cone classes are present, and medium-wavelength cones dominate. Photograph courtesy of L. Peichl.

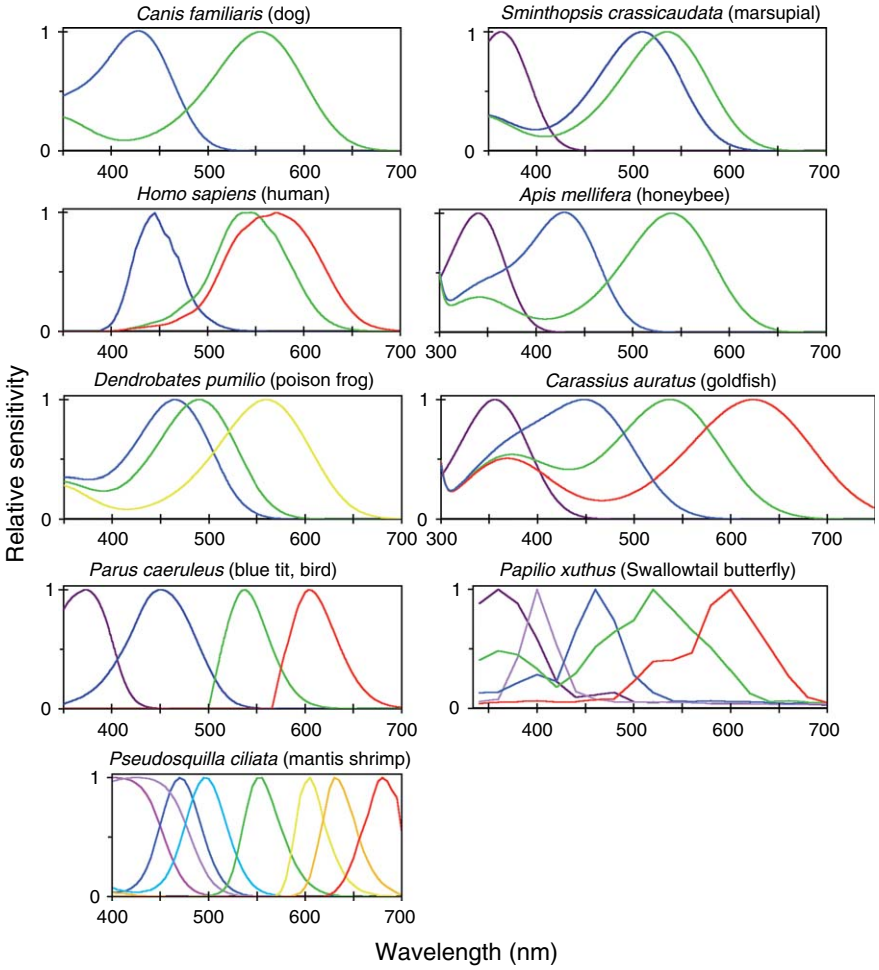

Figure 8 Color-vision systems of a variety of animals, all of which are active in the bright light of day either in terrestrial environments or in shallow water, and all of which have been demonstrated behaviorally to have true color vision. Note the extreme variability in receptor number and placement; even the three mammals that are illustrated near the top are quite different from each other. Data sources are as follows: *Canis familiaris* (visual pigments; Neitz, J. *et al.*, 1989); *Sminthopsis crassicaudata* (visual pigments; Arrese, C. A. *et al.*, 2002); *Homo sapiens* (spectral sensitivities; Stockman, A. *et al.*, 1993); *Apis mellifera* (visual pigments; Peitsch, D. *et al.*, 1992); *Dendrobates pumilio* (visual pigments; Siddiqi, A. *et al.*, 2004); *Carassius auratus* (visual pigments; Palacios, A. G. *et al.*, 1998); *Parus caeruleus* (computed sensitivities; Hart, N. S., 2001b); *Papilio xuthus* (spectral sensitivities; Arikawa, K., 2003); *Pseudosquilla ciliata* (computed sensitivities; Cronin, T. W. and Marshall, N. J., 1989).

the contributing pigment classes are spectrally placed to maximize the discriminability of objects likely to be viewed. A problem with this approach is that such objects have different sizes or probabilities of being in view, and they have different levels of biological significance. Initially, models were limited to relatively simple visual tasks, examining the performances of hypothetical pairs of cone types viewing pairs of spectra. In a pioneering study (Lythgoe, J. N. and Partridge, J. C., 1989), data were collected from objects in a typical forest (leaves and litter), and the cone pairs that provided the greatest variation in chromaticity (a measure of color value) of such objects correlated well with actual cone sets of arboreal mammals. This research team followed up with a more sophisticated approach that attempted to evaluate the ability of cone sets of animals in the relatively simple visual world of coastal water to discriminate objects in the foreground from a generalized background, either open water or an average spectrum of underwater plants. The best pairs of cone types were very similar to dichromatic sets found in common marine coastal fishes (Lythgoe, J. N. and Partridge, J. C., 1991).

More recently, technical advances have made it possible to examine spectral tuning of dichromatic color-vision systems with respect to the properties of entire scenes they are likely to view. Imaging spectroradiometry captures spectra of objects throughout a field of view, and the resulting data sets are free from bias concerning what objects to include in any analysis. Chiao C.-C. *et al.* (2000b) used this technique in a study of dichromatic vision in animals that inhabit temperate and tropical forests or that live on coral reefs in shallow marine waters. The optimal tuning systems they identified corresponded well with those of animals inhabiting either type of habitat. In a further analysis, they also found that the *in vivo* proportions of the two cone types were optimal for discrimination underwater by fish, but less than optimal for vision in forests by mammals (Chiao, C.-C. *et al.*, 2000b). The last result demonstrates that even in quite simple color-vision systems, spectral tuning is not the only factor controlling retinal design. Another wrinkle is that the proportions of receptor classes often vary across the retina, with many more short-wavelength-sensitive types occurring in the ventral than in the dorsal regions (Peichl, L., 2005). This could relate to spatiospectral properties of the visual field, but this has not been conclusively demonstrated.

The most complex receptor sets for which tuning has been successfully modeled are the trichromatic systems of honeybees and of Old World primates (like humans, see Figure 8). Both visual systems are used in day-active animals, but they are surprisingly different in their components, as honeybees have a receptor type responding deeply in the UV, lacked by primates, which in turn have a type that is tuned to wavelengths somewhat longer than the spectral range of bees. The spectral spacings of the two sets are also quite different.

The unusual features of human color vision (and of our anthropoid relatives) have received particular attention. The trichromatic color-vision systems of humans and Old World primates are nearly identical, based on sets of cone photoreceptors that are most sensitive in the blue (~425 nm), green (~535 nm), and yellow (~565 nm) (Mollon, J. D., 1989; Jacobs, G. H., 1993; Dulai, K. S. *et al.*, 1994; Shuye, S.-K. *et al.*, 1995; Jacobs, G. H., 1996). Vision in primates has been modeled using collections of spectra of objects that primates are known to favor, such as fruits or fresh foliage, as well as by examining the spectral and spatial properties of scenes likely to be of interest to primates. These studies confirm that primate color vision is highly adaptive for discriminating fruits from leaves, for discriminating ripe from unripe fruits, and also for discriminating young, nutritious leaves from older and less palatable ones (Mollon, J. D., 1989; Bowmaker, J. K. *et al.*, 1991; Osorio, D. and Vorobyev, M., 1996; Dominy, N. J. and Lucas, P. W., 2001; Regan, B. C. *et al.*, 2001; Párraga, C. A. *et al.*, 2002). Thus, primate color vision could have originated due to its advantages for locating palatable leaves, and this could have been followed by a lengthy coevolutionary sequence of fruit colors and tuning of color vision. Color vision of New World primates differs in important details from the human type; while the overall story is too lengthy and complex for this review, the references cited above should be sought for further information.

One disadvantage of devoting several receptor classes to color vision is that spatial acuity and color discrimination become entangled when adjacent receptors provide different signals – is the difference due to varying color or varying brightness in a scene? In primates, the 535 and 565 nm cone types provide information that is largely redundant for most classes of natural stimuli (but not the ones of special interest, noted above), reducing the ambiguity (Osorio, D. and Bossomaier, T. R. J., 1992; Nagle, M. G. and Osorio, D., 1993). Nevertheless, errors are not eliminated, and these clearly compromise spatial vision (Osorio, D. *et al.*, 1998; Regan, B. C. *et al.*, 2001).

An additional question concerning the design of primate color-vision systems is the means by which cone classes become correctly connected within the neural networks of the retina. Color vision could assemble nearly automatically by exploiting the spatial center-surround organization already in place. However, recent work suggests that this is not the case (Jusuf, P. R. *et al.*, 2006), so how new cone classes (such as the red receptors of Old World primates) become incorporated into preexisting color-vision systems is not currently understood. In Old World primates, color information is carried in two opponent channels, blue versus yellow (much like the original mammalian system) and red versus green. Spatiochromatic analysis of natural scenes indicates that these are entirely appropriate (Figure 9), with the red–green signals carrying the least informative (but potentially most biologically significant) signals (Ruderman, D. L. *et al.*, 1998; see also Buchsbaum, G. and Gottschalk, A., 1983).

The ecology of bee color vision has been examined using similar approaches. In a series of important papers, Lars Chittka and his coworkers proved that honeybee vision is optimal for discriminating among

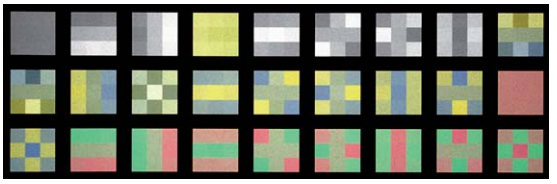

Figure 9 Spatial principal components of 3 × 3 pixels taken from multispectral images of natural scenes, and derived using the blue, green, and red sensitivities of the human eye using Stockman A. *et al.* (1993) sensitivities (see Figure 6) as described in Ruderman D. A. *et al.* (1998). Panels are arranged from left to right and top to bottom in order of decreasing contribution (eigenvalue). Note that all panels contain information from only a single visual channel (luminosity (gray), blue/yellow opponent, and red/green opponent), suggesting that the color channels of human color vision are well designed to optimize information analysis of natural scenes. Note also that the most significant components contain only luminosity, followed by blue/yellow (the typical mammalian color-vision system) and finally red/green (found only in primates). (See Ruderman, D. A. *et al.*, 1998 for further information.)

flowers (Chittka, L.and Menzel, R., 1992; Chittka, L. *et al.*, 1993). Paradoxically, however, the bee-type system is evolutionarily older than flower pollination (Chittka, L., 1996a), and trichromatic systems like those of bees are good for discriminating not only flowers, but also foliage, and thus have general utility to terrestrial insects (Chittka, L., 1996b; Briscoe, A. D. and Chittka, L., 2001). As in primates, the color classes of bee receptors work best in opponency to each other (Chittka, L. *et al.*, 1992; Chittka, L., 1996b).

There is good reason for animals like bees or primates, whose visual spectrum spans ~300 nm, to have a maximum of three receptor spectral classes. Visual pigment sensitivity spectra are fairly broad, so more than three receptor types provide no additional information (Barlow, H. B., 1982; Bowmaker, J. K., 1983). In fact, primates commonly become cone monochromats when they assume a nocturnal lifestyle (Jacobs, G. H., 1995), as do pinnipeds and cetaceans in the sea (Fasick, J. I. *et al.*, 1998; Peichl, L. *et al.*, 2001; Newman, L. A. and Robinson, P. R., 2005). But many animals, including vertebrates other than mammals, have a visual spectrum that exceeds 300 nm, commonly extending from 350 nm (in the UV) through 700 nm (Figure 8). Many such animals have four (or more) spectral receptor types, providing tetrachromatic color vision.

The great majority of bird species, and probably all passerines (perching birds), have four spectral classes of cones (Chen, D.-M. and Goldsmith, T. H., 1986; Jane, S. D. and Bowmaker, J. K., 1988; Hart, N. S., 2001a; 2001b). Surprisingly, terrestrial birds all have rather similar sets of photoreceptors – the major difference is the spectral peak of the shortest-wavelength receptor class, either in the violet or in the UV (Hart, N. S., 2001a; 2001b). However, there is some predictable variation in the abundances and distributions of the various cone sets (Hart, N. S., 2001a). The four cone types contribute to at least three opponent channels (UV/blue, blue/green, and green/red; see Goldsmith, T. H. and Butler, B. K., 2005). Modeling visual function in a 4D color-vision system is obviously tricky, and thus far has been tackled for relatively simple tasks (Vorobyev, M. *et al.*, 1998; Hart, N. S. and Vorobyev, M., 2005). However, this work shows that the colored oil droplets used as spectral filters in avian cone receptors improve color discrimination and possibly color constancy as well. In general, it appears that tetrachromacy in birds provides a basic visual competency that requires little tuning for species-specific tasks.

The spectrally most complicated color systems among vertebrates unexpectedly occur in fishes. Tetrachromacy in the lowly goldfish was recognized some time ago (Figure 8), although the visual ecology of the system is uninvestigated (Hawryshyn, C. W. and Beauchamp, R., 1985; Neumeyer, C., 1992). As of yet, the genetics underlying the complexity and the taxonomic distribution of receptor classes among fishes are not well understood, but recent work finds that the most ancient vertebrates already possessed a number of opsin genes available for future evolutionary elaboration (Collin, S. P. *et al.*, 2003; Trezise, A. E. O. and Collin, S. P., 2005). These have multiplied in modern cichlids, and perhaps other fishes, to as many as seven different cone opsins, expressed in different combinations among species (Parry, J. W. L. *et al.*, 2005). Sometimes, all seven appear in the retina (though some classes could be expressed only weakly). Ironically, even though modeling of color vision began with dichromatic fishes, the complexity found in many teleosts still evades explanation. The cichlids appear to customize their color vision, perhaps even at the level of individual animals, by selective expression of subsets of available opsin genes (Carleton, K. L. and Kocher, T. D., 2001; Parry, J. W. L. *et al.*, 2005), and this tactic for generating diversity in vision could be common in modern fishes (see also Fuller, R. C. *et al.*, 2004). Whether other animals, either vertebrates or invertebrates, have similar, genetically based tuning systems for color vision is unclear, but the extreme polymorphism within species makes it difficult to form generalizable hypotheses

about the functional basis of a given color-vision system. The visual ecology of cichlids and other fishes with similarly flexible visual systems (e.g., bluefin killifishes) is currently an active research area, and one that has real promise for providing insight from a rather different perspective than previous work.

While few (and perhaps no) vertebrates have more than four operational cone receptor classes, many invertebrates exceed this number of receptor types. Flies, for instance, have five classes (Hardie, R. C., 1986), although it is not clear that all five take part in color vision. On the other hand, the five spectral receptors of some species of swallowtail butterflies (Figure 8) clearly do contribute to high-quality color vision (Arikawa, K. *et al.*, 1987; Kinoshita, M. *et al.*, 1999). The current record-holders for spectral diversity, somewhat unexpectedly, are a group of marine crustaceans known as mantis shrimp, or (more formally) stomatopods (Figure 8). These creatures have up to 16 different visual pigments, with a minimum of eight classes devoted specifically to color vision (Marshall, N. J., 1988; Cronin, T. W. and Marshall, N. J., 1989; Cronin, T. W. *et al.*, 1994a; Marshall, N. J. *et al.*, 1996; Cronin, T. W. *et al.*, 2000). Mantis shrimps are able to pack so many receptor classes into a restricted spectral sensitivity range (~400 nm to a maximum of ~725 nm for the eight color classes), breaking the limit of three or four types, because the receptors are arranged uniquely, incorporating receptor-specific, photostable spectral filters and receptor tiering to narrow each receptor's spectral sensitivity (Marshall, N. J. *et al.*, 1991; Cronin, T. W. and Marshall, J., 2004). Mantis shrimps have two independent mechanisms for adjusting their visual systems to the specific photic environments they inhabit, ranging across species from the shallow waters of coral reefs to depths well over 100 m. Evolutionary tuning produces species-specific assemblages of visual pigments and photostable filters that provide a general fit to the local irradiance spectrum (Cronin, T. W. *et al.*, 1994a; 1996; 2000; Cronin, T. W. and Caldwell, R. L, 2002). The resulting spectral sensitivity functions are not necessarily fixed, however, as some mantis shrimp species can flexibly tune receptor sets to changing environmental conditions, in essence self-adjusting their visual systems to meet local requirements (Cronin, T. W. *et al.*, 2001; 2002; Cheroske, A. G. *et al.*, 2003; 2006). The functions of this complex and tunable color-vision system are not fully understood, providing a challenging problem for current and future visual ecologists.

As already noted, the visual spectrum of many animals extends into the UV, sampling wavelengths down to 350 nm or even shorter. While originally surprising, given the traditionally anthropocentric view of sensory physiology, UV photosensitivity turns out to be widespread among invertebrates and is found in all vertebrate classes (see Jacobs, G. H., 1992; Goldsmith, T. H., 1994). UV vision generally is incorporated seamlessly into color-vision systems, often adding a new opponent channel, as in birds. However, UV signals (discussed later in the chapter) are commonly involved in mate choice decisions, especially among vertebrates, so they do seem to have a special meaning in this sense (see Hunt, S. *et al.*, 2001).

Underwater, UV light is heavily scattered, but nevertheless is capable of penetrating at visually useful intensities to depths beyond 100 m (Frank, T. M. and Widder, E. A., 1996). Short-wavelength light thus can contribute to color vision and visual signaling in the sea (a concept that was long denied, a perception apparently originating from the observation that organic solutes in freshwater and coastal waters really do absorb UV light quite rapidly). The scattering of UV light in water provides a bright UV background, especially in shallow water, that can be exploited to enhance vision of nearby objects, making them stand out in silhouette (Figure 10). UV vision is common in shallow-water invertebrates (e.g., Cronin, T. W. *et al.*, 1994b) and fishes (Losey, G. S. *et al.*, 1999), where it is probably used to visualize objects that otherwise blend well into the underwater light field. UV vision should be particularly helpful for planktivores, which often feed by swimming up in the water column, attempting to spot their tiny prey against downwelling light.

1.08.4.3 Polarization Vision

As with UV sensitivity, humans are not sensitive to polarization properties of light and therefore tend to overlook the possibility that other animals may be sensitive to them. In reality, the huge majority of invertebrate species, and a number of vertebrates as well, sense and at least partially analyze light's polarization properties. The detection of polarized light is possible because the visual pigments of all animals are inherently dichroic (i.e., they absorb one orientation of polarized light preferentially over others). As the visual pigment molecules lie in the membranes of the receptor cell, the absorption axis of the chromophore extends roughly parallel to the membrane's surface. Membranes in rod and cone photoreceptors of vertebrates lie in stacks of planar structures, either

Green (490–560 nm) Ultraviolet (350–380 nm)

Figure 10 Images taken simultaneously at a depth of ~10 m on a site on the Great Barrier Reef, Australia through green-transmitting (Corning 4–64 filter, left) and ultraviolet-transmitting (Corning 7–60, right) glass filters. Note how the bright scattered background visible in the ultraviolet photograph silhouettes nearby fish and makes them far easier to see. The spectral ranges given beneath each panel are estimated from filter and lens transmission spectra and sensitivity of the film (Kodak Tri-X).

pancake-shaped disks (rods) or folded lamellae (cones) that are oriented perpendicular to the path of light, where the visual pigment molecules float freely (Cone, R. A., 1972). This arrays the chromophore dipoles orthogonally to incoming light, an advantage for capturing photons but a challenging situation for providing polarization sensitivity. The freely rotating visual pigments present a random array of absorbers with respect to their angular orientation, obviating polarization sensitivity (Figure 11, top left).

Nevertheless, a number of vertebrates display behaviors related to polarized light fields, and some show physiological responses to polarization features of a stimulus (reviews: Waterman, T. H., 1981; Hawryshyn, C. W., 1992; 2000; Horváth, G. and Varjú, D., 2004). In some species of anchovies, polarization sensitivity seems to be conferred by a set of specialized cone photoreceptors that lie on their sides, transverse to the optical axis of the eye and thus presenting their membranes parallel to light (Fineran, B. A. and Nichol, J. A. C., 1978; Novales Flamarique, N. and Harosi, F. I., 2002). There is also evidence that entopic phenomena may account for some cases of vertebrate polarization sensitivity; for instance, the visual sensation humans experience called Haidinger's Brush (see Minnaert, M., 1954). On the other hand, evidence from fish strongly suggests that some cone photoreceptors are polarization sensitive even when illuminated axially. Explanations require unusual optical phenomena in cones: graded-index-generated waveguide effects in elliptical cone inner segments (Rowe, M. P. *et al.*, 1994), grazing-incidence reflection in double-cone inner segments (Novales Flamarique, N. *et al.*, 1998), or tilted photoreceptive membranes (Roberts, N. W. *et al.*, 2004). Whether any, all, or none of these hypotheses will ultimately be accepted remains to be seen.

The situation in rhabdomeric photoreceptors of invertebrates like insects, crustaceans, or cephalopods is better understood. Their membranes are rolled into tiny tubes called microvilli that typically extend in groups from one margin of the receptor cell. In polarization-sensitive cells, all the microvilli are parallel, an anatomical arrangement diagnostic for polarization receptors. To permit polarization sensitivity, the absorption dipoles of visual pigment molecules also must be roughly parallel to the microvillar axis (Figure 11, top right). Unlike the freely moving visual pigments of rod and cone membranes, visual pigments in microvillar membranes are nearly immobilized within the microvillar membranes (Goldsmith, T. H., 1975; 1977; Goldsmith, T. H. and Wehner, R., 1977; Lillywhite, P. G., 1978; Doujak, F. E., 1984). Even reducing visual pigment concentration by 95% does not affect either the general alignment of the molecules or the polarization sensitivity of the receptor cell (Speck, M. and Labhart, T., 2001), implying that the molecules are well anchored, perhaps to cytoskeletal components such as the actin backbone or spectrin-like membrane proteins within the microvillus.

Ocular specializations can improve polarization sensitivity; an excellent example is the use of oriented mirrors or tapeta in spider eyes to direct light of a given polarization orientation to the appropriate receptors (Dacke, M. *et al.*, 1999; 2001). A variety of modifications can improve the polarization sensitivity of the microvillar receptors themselves (Figure 11), including extreme alignment and parallelism of microvilli throughout the receptor, thin layering of microvilli in

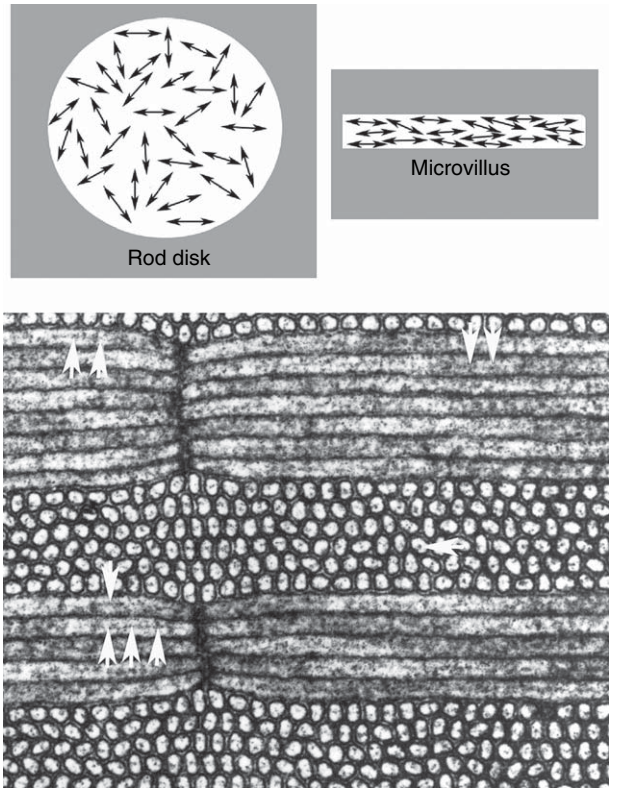

Figure 11 Top left: Schematic drawing of a rod disk as seen from the direction of approaching light *in vivo*. The double-headed arrows indicate the absorption dipoles of visual pigment molecules as they float in the membrane and freely rotate. Note that there is no preferred direction of orientation, so that all orientations of polarized light would be absorbed to similar amounts. Top right: Similar schematic of a microvillus, showing how the absorption dipoles tend to lie roughly parallel to the microvillar axis, providing an inherent preferential absorption to light with its electric vector polarized parallel to the microvillus. Bottom: Electron micrograph of polarization-sensitive photoreceptors of the mantis shrimp *Neogonodactylus oerstedii*, to show the alternating, orthogonal arrangements of microvilli in thin layers. The long, parallel microvilli extend parallel to the plane of the section, while the circular profiles are microvilli cut in cross section. The alternating layers are derived from different sets of photoreceptor cells, providing a two-axis polarizational analysis system. The white arrows show the actin cores of microvilli, which stabilize their structure. Photograph courtesy of C. A. King-Smith.

orthogonal polarization classes, and maximal dichroism of the receptor pigment itself (Snyder, A. W., 1973; Snyder, A. W. and Laughlin, S. B., 1975; Nilsson, D.-E. *et al.*, 1987). Polarization sensitivity can, of course, be further enhanced beyond the receptor level by post-receptoral processing (Saidel, W. M. *et al.*, 1983; Glantz, R. M., 2001). As noted earlier, the inherent polarization sensitivity of rhabdomeric photoreceptors can create stimulus ambiguity when spectral and polarizational features of a stimulus are mixed, so some invertebrate photoreceptors are structurally modified to destroy polarization sensitivity, while other species may evaluate viewed objects by combining spectral and polarizational cues.

Until recent years, polarization sensitivity throughout the animal kingdom was associated with behavioral tasks related to orientation or navigation. For example, honeybees have long been known to use patterns of polarization in the sky for travel between the hive and places of foraging, and many other insects orient themselves using celestial polarization cues (see reviews of Rossel, S., 1989 and Wehner, R., 2001). A similar capacity, using underwater light fields, could exist in salmonid fishes (Hawryshyn, C. W. and Bolger, A., 1991; Hawryshyn, C. W., 1992; 2003). Even some species of nocturnally migrating birds apparently calibrate their compasses using skylight polarization patterns, as they become disoriented when provided with a depolarized celestial pattern during twilight (Helbig, A. J., 1990). In another set of polarization-controlled orientation behaviors, water beetles and many other

insects recognize water surfaces by the horizontally oriented polarization reflected from them (Schwind, R., 1984; 1991), initiating responses that can bring about disaster when the polarization cue originates from artificial or oily flat surfaces (Horváth, G. and Zeil, J., 1996; Kriska, G. *et al.*, 1998). On the other hand, flying insects can use polarization to discriminate natural water surfaces from mirages or other virtual surfaces (Horváth, G. *et al.*, 1997). Finally, polarization vision plays roles in prey detection and in communication, topics to be covered later in the chapter.

1.08.4.4 Eye Movements

Eyes that produce quality images see only a portion of the visual world at any one time, and the region that is inspected in detail by the fovea (if present) is even smaller. So eyes must move to cover areas of interest, to follow objects in view that are themselves moving, to stabilize themselves in a moving panorama, and sometimes even to acquire visual information itself. Animals like humans, whose eyes are quite mobile within the head, are relatively uncommon; in most animals, the head itself does most of the moving that is responsible for shifts of gaze, and in many cases the animal as a whole makes the responsible movements. Engineers have paid special attention to how movements of the eyes are controlled, as the feedback channels and mechanisms of guidance can guide design of artificial, cybernetic systems. Eye movements also are interesting to visual ecologists, as the visual requirements of different species dictate different patterns of movement, which can give insight into visual needs and into the visual worlds these animals occupy.

Eye movements can be generally sorted into two general classes (Figure 12): those that stabilize the visual world or a portion of it and those that deliberately move the eye with respect to the world (see Land, M. F., 1995; 1999; Land, M. F. and Nilsson, D.-E., 2002). Perhaps the most fundamental eye-stabilizing behavior is optokinesis, in which the eye (or head, or body) turns in synchrony with a smoothly moving visual field. The field movement is most commonly generated by linear or angular movements of the animal itself, but can also be produced by steady flow as in natural waters. The compensatory behavior, called optokinetic nystagmus, involves an alternating series of smooth drifts of the eye to follow the visual field and quick returns in the reverse direction to permit further smooth drifts (Figure 12). During the saccadic return movement, the visual system is transiently blind. Optokinesis can be influenced by mechanical or vestibular inputs, or even by leg movements in crabs (Nalbach, H.-O.,

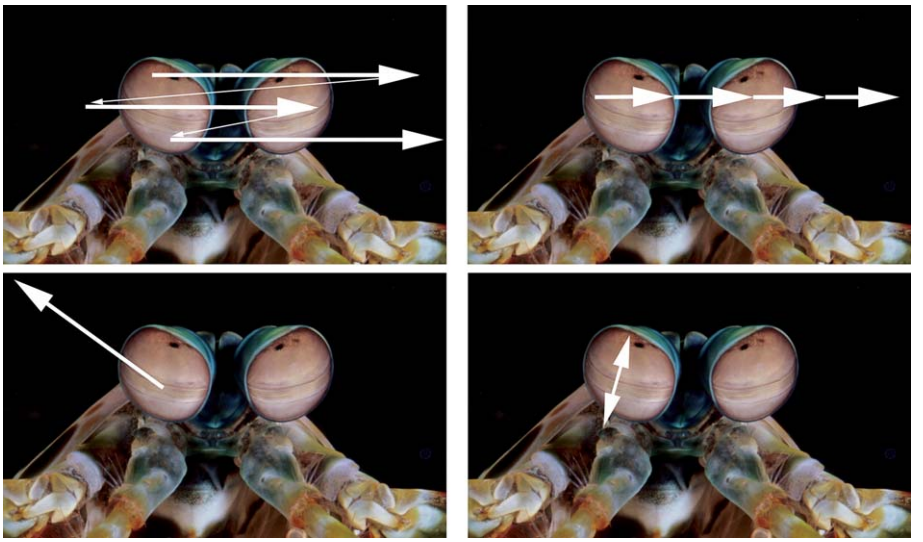

Figure 12 The major classes of eye movements, using the compound eyes of the mantis shrimp *Odontodactylus scyllarus* for illustration. The arrows show the direction and distance of movement. Top left: Optokinesis. The thin arrows represent the rapid returns occurring during optokinetic nystagmus. Top right: Saccadic tracking (for smooth tracking, only one long arrow would be drawn). Bottom left: Large fixation saccade. Bottom right: Scanning (note that the axis is perpendicular to the band of ommatidia forming the equator of the eye). Reproduced by permission of R. L. Caldwell.

1990), but its fine control is generally visual. This creates something of a paradox, as the movement itself is driven by the sliding of visual stimuli across the retina, and extremely high-gain systems required to minimize such slip are inherently unstable (see the original work on crustaceans by Horridge, G. A. and Sandeman, D. C., 1964). Nevertheless, visual control systems perform acceptably under natural conditions.

A second class of visual stabilizing movements involves tracking a small object moving within the larger visual field. This familiar visual task offers subtle but serious problems – the tracked object moves within the background field that normally serves to stabilize vision. Thus, the optokinetic system must be overcome during tracking, or retinal slip will instantly engage a countering response. Many animals switch effortlessly between optokinesis and visual tracking (consider the situation when you look out of the window of a moving vehicle, first letting the eye drift with the scene and then concentrating on a flying bird or other small, moving detail), but the control systems that permit this are by no means trivial (see Niven, J. E., 2006). Visual tracking can be smooth, driven either by the velocity of slip of the target on the retina (as in optokinesis) or by the angular displacement of the retinal location of the target from its desired fixation point (see Collett, T. S. and Land, M. F., 1975, for a classic study in hoverflies). Or it can be saccadic, occurring in a series of jumps reminiscent of the return phase in optokinetic nystagmus, but continuing in the direction of the target and following its movements in space (Figure 12). Praying mantises track prey smoothly against simple backgrounds but revert to a series of saccades when the background is spatially complex (Rossel, S., 1980). Or tracking may switch between smooth and saccadic eye movements with target position or speed (Cronin, T. W. *et al.*, 1988).

Of course, eye movements can be called upon to shift the visual field deliberately. At a minimum, if an animal wants to inspect particular locations in visual space without having a particular, moving target in mind, it still must escape optokinetic control; this is generally done by generating a saccade to the next fixation point. Many visual saccades occur simply because an animal wants to look here and there, perhaps checking for the presence of predators or to search for prey. Other visual shifts are smooth and continuous, and the visual system continues to operate throughout the movement. Peering behavior is a good example of this, where an animal like a praying mantis sways from side to side, generating relative motion flow between nearby objects and more distant ones and thereby gaining both absolute and relative depth information (Collett, T. S., 1978). Flying bees gain similar information as objects drift backward beneath their eyes at different angular velocities due to their different heights (Lehrer, M. *et al.*, 1988). In fact, much of their knowledge of space and its structure comes to bees via motion cues generated during flight (see Vladusich, T. *et al.*, 2005 for a recent report).

Slow visual scans make up a unique class of deliberate visual movements, found in only a few animals. We humans sometimes have the impression that we are scanning the environment, but this sort of visual behavior, which is common to many (if not most) animals, actually consists of a series of small saccades to stable fixation points. True scans are different; the speed of the eye's movement is relatively slow and is matched to the response time of individual receptors (Land, M. F., 1982; Land, M. F. *et al.*, 1990; Land, M. F., 1999). These movements occur in animals that have a linear retina consisting of a parallel array of a few rows of receptors, and the scans are perpendicular to its long axis translating the retina's view through visual space. In jumping spiders, the retinas of just the principal eyes (of four pairs, the ones with by far the best vision) sample a tiny region in front of an animal by scanning back and forth, looking for particular patterns signifying the presence of a potential mate (Land, M. F., 1999). Stomatopod crustaceans, whose eyes have both an extended and a linear retina, have to time share, alternating stabilizations or tracking movements and scans, which paint color and polarization information onto the extended visual field of the peripheral retina (Figure 12). This seems an awkward situation, and it requires an unusual system of driving muscles (Jones, J., 1994), but these mantis shrimps are fearful visual predators in shallow marine waters. There are many ways of seeing, and the fact that some animals have eye movements that seem awkward or inefficient probably means that we just do not understand them.

1.08.5 The Role of Vision in Behavior

1.08.5.1 Orientation

Little is needed for a photoreceptor organ to signal light's intensity and to provide basic information about the direction from which the light arrives (see Nilsson, D.-E. and Pelger, S., 1994). A simple pit lined with photoreceptive cells and backed with a layer of light-absorbing pigment can serve this task, or there may be various optical elaborations, but for many animals an eye need do no more than this: signal light's

intensity and general direction. Knowing these, daily activity patterns and orientation within a directional light field are possible. The vertical migratory behavior of plankton, reputedly the greatest rhythmic movement of life on earth, is mostly controlled by such simple eyes (Forward, R. B., Jr., 1976; Lenz, P. H. *et al.*, 1996). Even the multiple and optically advanced (but defocused) eyes of cubomedusans (Nilsson, D.-E. *et al.*, 2005) apparently serve only to permit station-keeping and obstacle avoidance among mangrove roots.

Of course, most animals larger than plankton, as well as some planktonic creatures, use more sophisticated orienting visual technologies. The widespread ability to use celestial polarization patterns, both during the day and at night, has already been remarked. Also noted earlier is the ability of many insects to orient to water surfaces using polarization reflections. These behaviors do not require particularly excellent eyes. In fact, celestial polarization orientation is generally provided by one area of each compound eye – the dorsal rim – that feeds three information channels produced by massive spatial integration (Rossel, S., 1989; Labhart, T. *et al.*, 2001). These extremely wide-field polarization sensors have the advantage of good performance even when much of the sky is obscured by canopy or clouds. In some species they can foster polarization orientation at nocturnal skylight intensities. Lacking compound eyes, some spider species use wide-field optical compasses, based on polarization detection, that are built from tiny simple eyes (Dacke, M. *et al.*, 1999; 2001).

Obviously, there are many other, and far more complicated, orienting and navigating strategies available to animals that use visual information, but discussing these would range well beyond the scope of this chapter and even beyond the usual borders of what constitutes visual ecology. An excellent and extensive literature exists on landmark navigation in animals, and navigating insects have often been considered as models upon which to base autonomous, artificial devices that evaluate landmarks, optical flow fields, and celestial polarization (see, for instance, Lambrinos, D., 2000). An unusual variant on landmark orientation has been found in forest-living ants, where the landmarks are actually patterns of light and foliage seen in the forest canopy (Hölldobler, B., 1980). Such a simple and elegant strategy should be ideal for many forest dwellers with small (or big) brains and eyes, but its use has not been identified in any other animal.

1.08.5.2 Predation and Its Avoidance

The conflict between predators and prey is nearly as ancient as life itself, and certainly predates the appearance of vision. The appearance of good visual organs, probably in the late pre-Cambrian, instantly accelerated the arms race between the two parties. In fact, early visual evolution likely initiated the rapid Cambrian explosion, when many new body plans and modes of life suddenly turn up in fossils (Parker, A. R., 1998; Land, M. F. and Nilsson, D.-E., 2002). Having good eyes benefited both predators and prey, but with vision progressing on both sides of the interaction, animals became evolutionarily obligated to ever-greater efficiency at both detecting others and escaping (or capturing) them. In reality, so many aspects of visual design relate to predation that only a superficial discussion is possible here. For a comprehensive recent review, see Cronin T. W. (2005).

Predators and prey have very asymmetrical interests. While the predator can usually survive a failed attempt to capture prey, a prey animal must always successfully evade its predator. Further, a predator need concentrate on only one prey at a time, while prey animals must detect every potential predator. Thus, eyes of prey generally have very extensive visual fields, most often sampled by eyes that are placed on the sides of the head. Foraging birds provide perfect examples. Woodcocks see almost the entire horizontal plane (Martin, G. R., 1994), and shoveler ducks view essentially the entire hemisphere above the horizon (Guillemain, M. *et al.*, 2002); both woodcocks and shovelers actually have binocular visual fields to front and rear. Prey animals that inhabit flat worlds, like plains animals, fish on the seabed, or animals living on mudflats, have their most acute vision right along the horizon. Such a specialization requires clustering of retinal ganglion cells along the equator of the eye in vertebrates, forming a visual streak (see Walls, G. L., 1942; Land, M. F. and Nilsson, D.-E., 2002). Compound eyes similarly can cluster their ommatidial axes near the horizontal plane, producing a different kind of visual streak. Fiddler crabs inhabit flat expanses of beach, and their compound eyes sample intensively along the horizon (Zeil, J. *et al.*, 1986; 1989; Land, M. F. and Layne, J. E., 1995). In fact, fiddler crabs live by a simple rule: if something in view breaks the line of the horizon or is above it, it is a predator.

Predators need not sample every point in the environment for the presence of prey, but it is certainly advantageous to spot prey and see them clearly at distances where the predator is still invisible. This

explains their frontally directed eyes, often with extensive binocular overlap for visual attention and distance estimation. These eyes can achieve outstanding spatial acuity, provided by foveas or acute zones that specialize in just a bit of the visual world (Figure 5). Some predators have double foveas in each eye, as noted earlier, one looking ahead and the other laterally. Searching birds rigorously stabilize the visual field on their retinas when stalking, holding the head steady as long as possible and then rapidly thrusting it forward to the next fixed position, no doubt to maximize the chance of spotting something (Cronin, T. W. *et al.*, 2005; Fujita, M., 2006). Tubular eyes, described earlier, expose their roles as prey detectors by their binocular visual fields and their concentration on a limited spatial region (Figure 4).

Localizing prey demands accurate depth measurement, too. Only a few vertebrate predators use true stereopsis, in which disparity between retinal images is used to generate a sense of depth, but monocular systems – especially accommodation – are widespread (Collett, T. S. and Harkness, L. I. K., 1982). Vertebrates from fish to mammals use focusing cues to range their attacks. Chameleons, famous for the robot-like movements of their turret eyes, use telephoto optics to form a large image with a shallow depth of focus, and thus can accommodate very accurately for distance measurements (Ott, M. and Schaeffel, F., 1985). Nearly identical optical engineering is found in the eyes of the sandlance, a piscine ambush predator (Pettigrew, J. D. *et al.*, 1999). Cuttlefish do not have telephoto eyes, but like the vertebrates to which they are often compared, they use accommodation to judge prey distance just before launching a tenticular attack (Schaeffel, F. *et al.*, 1999).

No matter what their calling, most animals benefit from being inconspicuous. This generally means looking like their surroundings or backgrounds – in other words, being camouflaged. In open water, the surroundings and background are the same, a spatially varying, but fully predictable, light field. Animals have found three ways to match this background: being transparent, reflecting downwelling light in the same spatial pattern as the background, or using bioluminescence to obliterate the silhouette they show from below (Nilsson, D.-E., 1997; Johnsen, S., 2001; 2002). These are all essentially contrast-reducing strategies, and they need not be perfect. Even a modest contrast decrease can significantly reduce visibility, providing a basis for the evolution of later, more sophisticated solutions (Land, M. F., 2000).

Camouflage more generally means dealing with a patterned background: fallen leaves and twigs, a pile of rocks, the trunk of a tree, and blotches on sand. The classic reference by H. B. Cott, *Adaptive Coloration in Animals* (1940), is still worth a good browse to review the stratagems used by animals. More recent work in visual ecology has examined how animals use system properties of vision and statistical features of natural scenes to generate effective camouflage. For example, spots and blotches used for crypsis are often outlined with a contrasting edge, tying into center-surround systems of edge enhancement and thereby verifying their presence as a background feature (Osorio, D. and Srinivasan, M. V., 1991). Some of the best model systems for examining biological camouflage are those that produce background matching on the spot, as used by flounders (Ramachandran, V. S. *et al.*, 1996) or cuttlefishes (Chiao, C.-C. *et al.*, 2005). The cues these animals use to create their nearly perfect patterns of concealment are not yet fully understood. The ability of cuttlefish to match backgrounds not only for spatial pattern but also for color is particularly puzzling, as the animals lack color vision (Marshall, N. J. and Messenger, J. B., 1996; Mäthger, L. M. *et al.*, 2006). Another surprising recent finding is that animals can use the same patterns and colors to be either conspicuous or cryptic, depending on how they allow themselves to be viewed. Forest-dwelling birds that display brilliant colors in patches of sun can become highly cryptic – nearly invisible – by moving a short distance away into the shade (Endler, J. A. and Théry, M., 1996). Similarly, the beautiful colors and patterns of reef fishes, obvious when seen from nearby, blend into the background of the coral reef at moderate distances (Marshall, N. J., 2000a; Marshall, N. J. and Vorobyev, M., 2003).

Color and pattern matching in camouflage are very difficult to break through, because natural selection shapes excellent matching very efficiently. The less-perfect systems available for hiding in midwater can be at least partially nullified, however. One solution to the problem has already been noted. Searching for reflective or transparent objects is improved using UV visual receptors that respond strongly to the background, scattered light, and allow prey to be visualized in silhouette (Figure 10). An alternative is to use polarization vision in the same way. The background light underwater is usually polarized, but animals either depolarize the light or reflect the light of different polarization. Squids and cuttlefish use their sensitive polarization vision to improve prey detection in such conditions (Shashar, N. *et al.*, 1998; 2000). It is

interesting to consider that, unlike the demonstrated benefits of polarization vision for predation in particular circumstances, color vision seems to be of little benefit to predators. This is probably true because the evolution of color camouflage is rapid and effective, quickly neutralizing improvements in color discrimination; polarization camouflage is a much more difficult evolutionary problem (and no example of polarization camouflage has ever been found). There is one case, though, where color vision is critically important to predators and that occurs when potential prey signal to predators that they are unpalatable or dangerous, so an attempt to consume them could have lethal consequences for the predator. These warning messages from prey to predator are known as aposematic signals, and these will be discussed in the next section.

1.08.5.3 Visual Signaling

As the earliest and simplest eyes gave way in many evolving lineages to more competent visual organs useful for orientation, predator detection, and other tasks like those discussed above, the improved vision also permitted new ways for animals to view other members of their own species. Visual signals must therefore have been used by many of the earliest animals that had complex body plans. In fact, the earliest well-preserved fossils of metazoans, from the Burgess Shale, already reveal evidence of functional color signals (Parker, A. R., 1998).

It seems obvious that visual systems of animals and the signals they view must coevolve (see Endler, J. A., 1992, 1993; Endler, J. A. and Basolo, A. L., 1998; Endler, J. A., 2000). Surprisingly few examples of coevolution of this type are documented, however. The only convincing cases of evolutionarily cooperative tuning of vision and signals are found in bioluminescent signaling systems, as in fireflies (Lall, A. B. *et al.*, 1998; Cronin, T. W. *et al.*, 2000) or deep-sea fish (Partridge, J. C. and Douglas, R. H., 1995; Douglas, R. H. *et al.*, 1999). A precise match between the single spectral channels in the eyes of these animals and the bioluminescent emissions of conspecifics is possible because the signaling environment is so simple. Essentially, there is little of visual interest in the dark surroundings of these signals, so it makes sense to shape vision to the signals and vice versa. In animals with a spectrally more complex – and typical – visual environment, visual systems (including color vision) are constrained by the need to carry out a variety of tasks; natural environmental properties limit evolutionary freedom. Even where there seems to be tuning of vision for special signaling tasks (e.g., species recognition, Bernard, G. D. and Remington, C. L., 1991; ovoposition, Kelber, A., 1999), there are so many spectral types of receptors present that it is difficult to make a case for strong selection on a particular class.

It therefore seems that the spectral mechanisms of most animals operate for many tasks, and are evolutionarily shaped by environments and fundamental properties of visual pigments and photoreceptor physiology. As noted before, the trichromatic visual system of honeybees probably appeared early in insect evolution, significantly predating the evolution of the flowers they pollinate (Chittka, L., 1996a; Briscoe, A. D. and Chittka, L., 2001). Bee vision is nonetheless nearly optimal for discriminating among flowers (Chittka, L., and Menzel, R., 1992; Chittka, L. *et al.*, 1993). The fitting of signals (in this case, flower colors) to preexisting visual systems (of insects) probably represents the typical evolutionary sequence. Similarly, the fruit colors that are well recognized and discriminated by the color-vision systems of primates with very diverse lifestyles and food preferences (Mollon, J. D., 1989; Osorio, D. and Vorobyev, M., 1996; Regan, B. C. *et al.*, 2001) imply that these colors were selected for their visibility to monkeys and apes. Birds, the canonical examples of colorful terrestrial vertebrates, fantastically diverse in their appearances, share very similar or even identical visual systems (Vorobyev, M. *et al.*, 1998; Hart, N. S., 2001a; 2001b). Looking at color vision and signals from a different perspective, the retinas of animals as different as birds and bees are so predictable that crab spiders hiding in flowers can match backgrounds (for crypsis) adaptively to become invisible to both avian predators and apian prey (Théry, M. and Casas, J., 2002). As a final example, a recent study that specifically examined the coevolution of signaling colors and color vision in stomatopod crustaceans found little evidence that vision was tuned to recognize signals (Chiao, C.-C. *et al.*, 2000c).

Visual ecological perspectives are of interest to almost anyone studying signals, but make up only a fraction of all studies of signal evolution. The general theory behind the evolution of signals, particularly visual signals, has been covered well by Endler J. A. (1992; 1993; 2000), and a recent book edited by Espmark Y. *et al.* (2000) discusses many current interests in the field of animal signals. Visual ecologists have concentrated on questions involving the function of the signal (information content), the nature of the signal (the underlying optics, pigment, and

structure), and particularly on the visual aspects of the signal (visual system of the viewer, environmental background, and lighting situation).

Animals signal to competitors that they are able to defend resources, to potential mates that they have the right stuff, and to potential predators that they are dangerous or toxic as prey. The ecological and social dynamics of such signaling appeal to evolutionary or behavioral biologists, but how the signals are tuned for best visibility and maximum visual impact obviously brings us back to sensory issues. The signals that appeal – or are even visible – to females can be explained by reference to their visual systems as well as to environmental backgrounds and lighting (Endler, J. A., 1991; Vorobyev, M. *et al.*, 1998; Siddiqi, A. *et al.*, 2004). Aposematic signals (warning colors) are unusually interesting in this regard, as they are the great exception to the general rule that color is irrelevant in predation. Here, the color is the signal (Sillen-Tullberg, B., 1985). In fact, the warning colors in some systems are so diverse and variable, as in the dart-poison frogs of the American tropics (Summers, K. *et al.*, 2003; Siddiqi, A. *et al.*, 2004), that the rule for a predator seems to be "don't eat any bright-colored frog"; the specific color (or pattern) expressed by the frog is perhaps irrelevant. Warning colors are so widely used that many predators innately avoid novel prey (Lindström, L. *et al.*, 2001).

Visual signals include many components: achromatic aspects, color pigments, structural colors, pattern, and movement. Of these, color and brightness have proven the easiest to analyze, but some work has begun on the meaning of pattern and on how movement ties into visual systems of intended receivers (see for instance Crook, A. C., 1997; Zeil, J. and Hemmi, J. M., 2006). Animal colors arise from an astonishing diversity of sources (Cott, H. B., 1940; Fox, D. L., 1976), pigments, either alone or in layers (including fluorescent ones), and structures, including interference reflectors, coherent scatterers, incoherent scatterers (see Prum, R. O. *et al.*, 1998; 2004), diffractive structures, and sophisticated photonic crystalline structures (Vukusic, P. and Sambles, J. R., 2003). The colors themselves carry information about the sender, because many pigments are thought to be costly to acquire and highly ordered structures probably signify that their builder is healthy and unusually free of parasites. The intensity and contrast of colors can be emphasized by adding fluorescent components emitting at wavelengths where the illumination itself is weak (Mäthger, L. M. and Denton, E. J., 2001; Arnold, K. E. *et al.*, 2002; Mazel, C. H. *et al.*, 2004; Figure 13). Some signals involve wavelengths that humans overlook, primarily in the UV, or provide polarization patterns invisible to humans and many other animals; these will be described further below. Making the signaling situation yet more complex, animals can change their appearances slowly or instantaneously, flashing their signals or making themselves inconspicuous (Lythgoe, J. N. and Shand, J., 1983; Shashar, N. *et al.*, 1996; Zeil, J. and Hemmi, J. M., 2006). And, as noted earlier, animals can change their appearances by moving into and out of varying lighting microenvironments as required.

Modeling how signals visually stimulate a given viewer under specific conditions of illumination and within specific visual environments has become

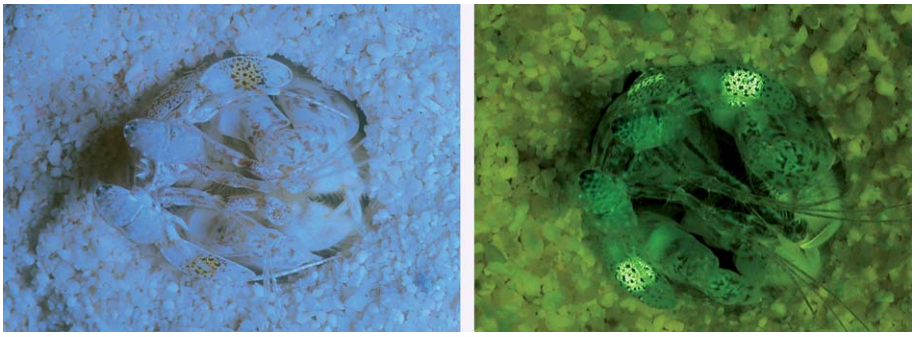

Figure 13 Fluorescent signaling in a mantis shrimp, *Lysiosquillina glabriuscula*. The left image shows a white-light-illuminated animal at its burrow entrance, while the right image shows the same animal illuminated with narrow-band blue light and photographed through a barrier filter that blocks the excitation light. Note how the yellow markings on the antennal scales (the flat plates extending to the right and left) look similar in both white (reflective) and blue (fluorescent excitation) illumination. Reproduced by permission of R. L. Caldwell.

routine. More recent approaches that have particular appeal involve attempts to recreate the appearances of signals as they might appear to a visual system of interest (e.g., Vorobyev, M. *et al.*, 1997; 2001; Marshall, N. J. and Vorobyev, M., 2003). The intent is not so much to enter the sensory world of an animal as to inspect the resulting images for guidance concerning which aspects of the signal seem special. A good example of this is illustrated in Figure 14, which shows the modeled appearance of a dart-poison frog as viewed by a human (to provide the appearance we see, for comparison), a bird (a model predator), and a conspecific frog (a potential mate). The patterns of coloration in these images suggest that the frog communicates with potential predators and with conspecifics using different signals aimed in different directions.

This section on the visual ecology of signals would not be complete without a mention of signals that animals use that we cannot see, based on patterns of reflectance of UV or polarized light. From one point of view, UV colors and patterns should be fundamentally similar to other color signals, although they do have the special property of being invisible to many visual systems. However, this is also true of very long-wavelength colors, specifically the reds, as they are also outside the spectral range of many mammals, insects, or other animals (Figure 8). UV signals frequently play critical roles in mate choice decisions by birds (Andersson, S. *et al.*, 1998; Bennett, A. T. D. *et al.*, 1996; 1997; review: Cuthill, I. C. *et al.*, 2000). UV patterns appear on the bodies of many reef fishes (Marshall, N. J., 2000b;

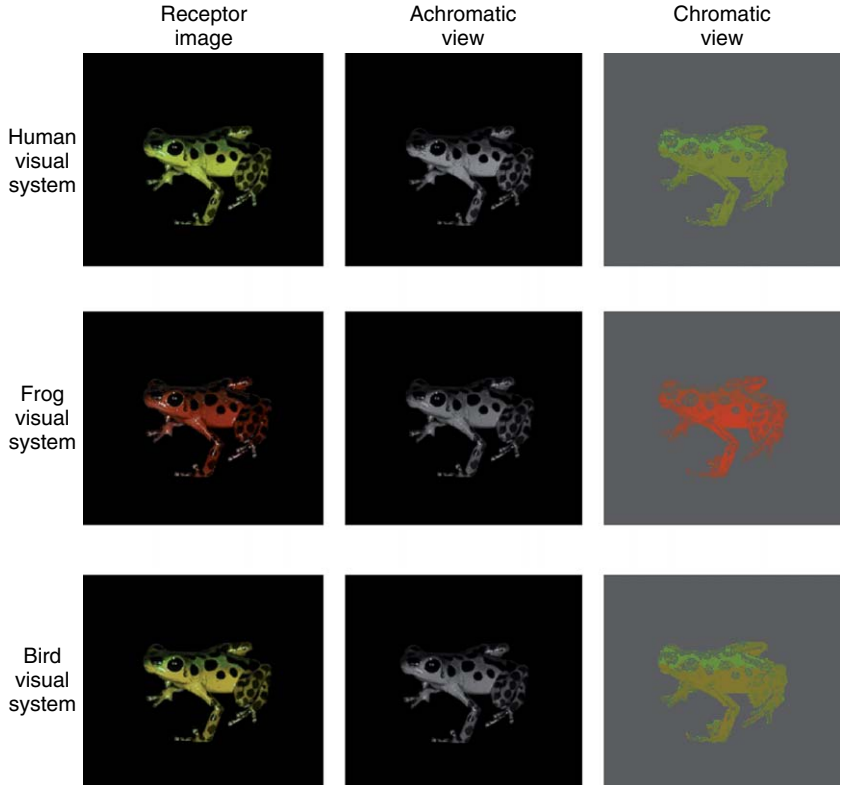

Figure 14 Reconstructed views of color signals in the dart-poison frog, *Dendrobates pumilio.* These images were derived by matching spectral reflectances to individual pixels of a digital photograph of the animal, using data obtained by Siddiqi A. *et al.* (2004). Each row of images portrays the computed view provided by the visual system indicated at the left, using the spectral sensitivities illustrated in Figure 6 (for the bird visual system, the modeling did not include the ultraviolet receptor class). The receptor image scales blue, green, and red pixel values to photon capture by the short-, medium-, and long-wavelength receptor classes of each species. Achromatic view shows photon capture only by the long-wavelength class (in birds, the double-cone class), which in each species approximates the intensity-only (luminosity) view. The chromatic view scales each pixel to a total intensity of 128 bits for the summed receptor channels, thus producing a roughly isoluminant image. Note that different color patterns are distinctive for the different visual systems; the human and bird are particularly sensitive to the dorsal green reflectance, while the frog system is most stimulated by the ventral yellow color.

Marshall, N. J. and Vorobyev, M., 2003), and have been demonstrated to be important in dominance interactions in damselfishes (Siebeck, U. E., 2004). It certainly seems possible that the high degree of structural or pigmentary integrity necessary to produce a good UV signal could be indicative of an animal's fitness, although this is not yet established.

Polarization signals have special features that differentiate them from typical color signals. For one thing, they are normally clearly visible only when viewed from the correct angle, so that linearly polarized light is reflected directly from the sender to the eye of the receiver. In butterflies, this should produce a flickering and presumably highly visible signal to conspecifics (Figure 15), and in fact, some tropical butterflies do use polarization reflections as mating signals (Sweeney, A. *et al.*, 2003). Most animals known to have polarization signals, however, live in the ocean. Here the use of polarization has very special advantages. First, unlike the case in air, few objects in water

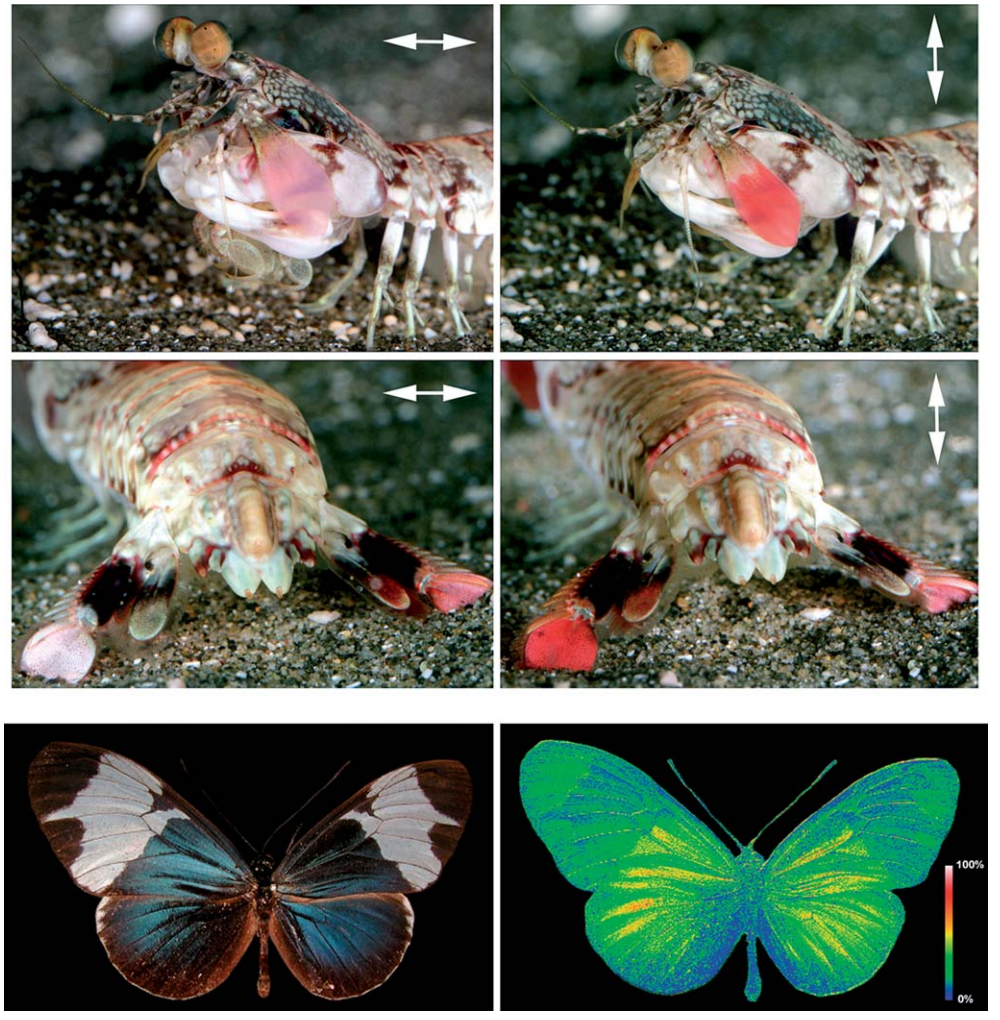

Figure 15 Polarization signals. Top image set: The stomatopod *Odontodactylus latirostris*, photographed through horizontal (left) and vertical (right) linear polarizers (direction of transmitted polarization is indicated by the double-headed arrows). Note the change in appearance of the antennal scale (upper two panels), the appendage extending down and to the animal's left, and of the uropod (lower two panels), the paddle-like appendage extending to the side. These appendages are displayed during mating or aggressive encounters, and the polarized reflections are thought to be intraspecific signals. Reproduced by permission of R. L. Caldwell. Bottom image pair: The tropical butterfly *Heliconius sappho*. The left panel shows a full-color image, while the right is an analyzed false-color image showing the percent polarization of reflected light (coded as indicated by the key). Note that the polarization pattern is quite unlike the color pattern. Photograph courtesy of J. Douglas.

reflect strongly polarized light, so a polarization signal should look distinctive when displayed. The second great advantage is that the relatively stable underwater lighting environment, where light arrives nearly always from overhead, produces a polarization reflection that is stable and constant over a range of depths. Signals based on color patterns are unreliable in water for this very reason; they change in appearance with changes in depth and water quality. Polarized-light signals are far more reliable. They are widely used by cephalopods, particularly squids and cuttlefishes (Shashar, N. *et al*., 1996; Shashar, N. and Hanlon, R. T., 1997). The other masters of underwater polarization communication are the mantis shrimps (Figure 15). These creatures have specialized polarization receptors in their compound eyes, and they use a wide diversity of polarization signals during mating and territorial interactions (Marshall, N. J. *et al*., 1999; Cronin, T. W. *et al*., 2003). It is reasonable to expect that biological signaling based on patterns of polarized light will turn out to be widespread among invertebrates, many of which are capable of good polarization vision.

1.08.6 Concluding Remarks

What other animals use their eyes for, and what they see, are questions that have interested humans since time immemorial. Today's visual ecologists have a varied and ever-changing set of tools to investigate animal vision and to begin to understand how animals get the information they need using their visual systems. Visual ecology provides the link between physiology and sensory biology and animal ecology, behavior, and social interactions. I have attempted to provide a feel for this vital and active field in this chapter, in the hope that this conveys some of the excitement experienced by researchers working on so many diverse topics stimulated by ideas on how animals view their worlds.

1.09.1 Introduction

The mammalian eye is a complex structure that has evolved to facilitate the extraction of information available in the photic environment. The process of seeing starts when light enters the eye through the pupil and reaches the photoreceptors at the back of the eye. These exquisitely specialized cells contain light-sensitive photopigments that absorb incident light and initiate the process of transducing light energy into a neural signal. Photons that are not absorbed by photopigments cannot contribute to sight, and so all higher-order visual analysis is conditioned by the successful execution of this fundamental step. This chapter examines the diverse family of mammalian photopigments by considering their structure, function, and evolution, as well as their role in color vision and in human retinal disease.

1.09.2 Structure of Photopigments

1.09.2.1 Photoreceptor Structure

The retinas of all mammals contain both rod and cone photoreceptors. In most mammals, rods greatly outnumber cones; in humans, for example, there are nearly 20 rods for every cone, but there are some mammalian lineages, such as the squirrels, in which cones are the predominant receptor type. Grossly, photoreceptors consist of an outer segment, an inner segment, and a synaptic terminal (Figure 1). The inner segment is the metabolic center of the photoreceptor, housing the nucleus, mitochondria, and other cellular machinery. Interposed between the inner and outer segments is the connecting cilium, a microtubule-based structure, through which all newly synthesized proteins (including photopigments) are transported from the inner segment to the outer segment. Visual

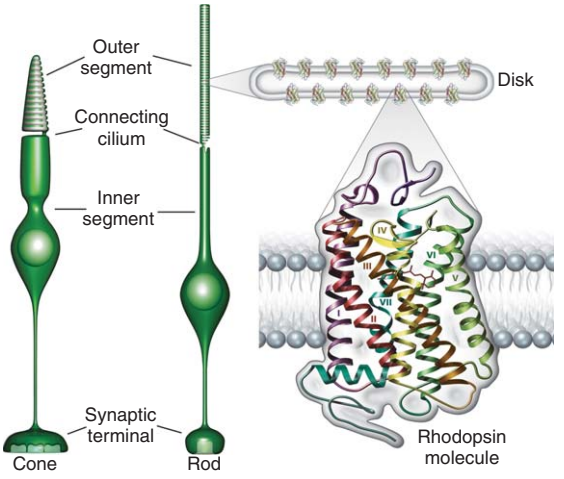

Figure 1 Basic structure of rod and cone photoreceptors. Both cells have an inner and outer segment, a cell body, and a synaptic terminal. The outer segment of both rods and cones consists of stacks of membranous disks. In cones, the disks are continuous with the plasma membrane of the cell, whereas in rods they are free-floating. The inset to the upper right illustrates the positioning of rhodopsin within the outer segment disk membranes, and the inset to the lower right is a magnified view of the molecule based on the rhodopsin crystal structure reported by Palczewski K. *et al.* (2000). Source: Figure adapted from WebVision, University of Utah reproduced with permission.

transduction takes place in the outer segment. The outer segment of both rods and cones consists of stacks of membranous disks – in cones, the disks are continuous with the plasma membrane of the cell, whereas in rods they are free-floating. Mammalian photopigments are integral membrane proteins located within the lipid membrane of these outer segment disks (see Figure 1). Photopigment is very abundant with some 100-million photopigment molecules being embedded throughout the outer segment of each rod and cone cell. It is estimated that photopigments represent about 90% of the protein molecules in the outer segment (Nathans, J., 1987; Rodieck, R. W., 1998; Filipek, S. *et al.*, 2003). Recent work suggests that photopigments either can exist as single molecules or can self-assemble into oligomeric complexes within the outer segment (Fotiadis, D. *et al.*, 2003; Filipek, S., 2005; Botelho, A. V. *et al.*, 2006). This higher-order arrangement appears in other members of the G-protein-coupled receptor (GPCR) protein family (see Angers, S. *et al.*, 2002; Park, P. S.-H. and Palczewski, K., 2005 and references therein). The functional consequences of assembly into higher-order structures are not completely understood, and with regard to photopigment oligomerization, there remains considerable controversy (Fotiadis, D. *et al.*, 2003; Botelho, A. V. *et al.*, 2006; Chabre, M. and Le Maire, M., 2006).

1.09.2.2 Protein Structure

Retinal photopigments consist of two parts: a protein (opsin) and a chromophore (in mammals, exclusively 11-*cis* retinal). The chromophore is covalently bound via a protonated Schiff base linkage with a specific lysine residue in the opsin (apoprotein) molecule (Wald, G., 1968). Opsins belong to the protein superfamily of GPCRs. GPCRs are the largest protein family known and serve to transduce extracellular signals (ligand binding) into intracellular signals (G-protein activation). All GPCRs share the structural motif of seven-transmembrane α-helical segments (for more detailed reviews see Okada, T. *et al.*, 2001; Menon, S. T. *et al.*, 2001). As depicted in Figure 1, about 50% of the opsin is within the bilipid membrane (Sakmar, T. P., 2003), while the C-terminal, N-terminal, and the short protein loops connecting the α-helices reside outside the membrane.

The photopigments in the mammalian outer retina can be placed into three main groups based on the wavelength of the maximum sensitivity (λ_{max}) of the pigment – rhodopsins, short-wavelength-sensitive (S) pigments, and long/middle-wavelength-sensitive (L/M) pigments. Mammalian rhodopsins typically have λ_{max} values of around 500 nm, whereas there is significant variation in the λ_{max} of the S and L/M pigments. As shown in Figure 2(a), mammalian S pigments have λ_{max} values that fall between about 360 nm and 445 nm, while mammalian L/M pigments have λ_{max} values between about 493 nm and 565 nm (Yokoyama, S., 1997; 1999; Ebrey, T. and Koutalos, Y., 2001). As described below, the exact amino acid sequence of the opsin determines the spectral differences between the photopigments.

For all mammals so far examined, the rhodopsin molecule is 348 amino acids in length, with a molecular mass of about 40 kDa. Mammalian S opsins vary in length from 346 to 350 amino acids, the human S opsin being 348 amino acids in length. L/M opsins are less variable, with most species (including humans) having L/M opsins that are 364 amino acids long. The additional length in the L/M opsins is found at the N-terminal where the conventional numbering of the protein starts. Thus, except for the N-terminal, all mammalian photopigments can be perfectly aligned. Given an amino acid position in one pigment, it is possible to identify the corresponding position in a pigment from either of the other two mammalian

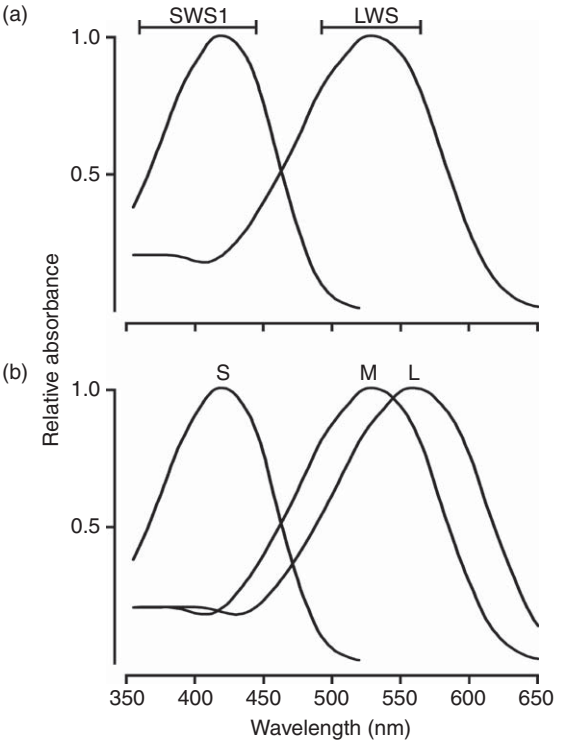

Figure 2 Spectral absorption curves for mammalian photopigments. (a) Mammalian SWS1 and LWS cone pigments have λ_{max} values that vary over wavelength ranges that are indicated by the extent of the horizontal bars (see text). (b) The photopigment complement found in most catarrhine (Old World) primates, conferring trichromatic color vision.

groups. The rule for the human pigments is to subtract 3 to identify the position in the S opsin that corresponds to a given position in rhodopsin or add 16 to find the corresponding position in the L/M opsins. The positions of all amino acids identified in this section are based on human rhodopsin numbering (Figure 3).

At the protein level, human rhodopsin is about 41% homologous with the S, M, and L opsins. The L and M pigments are about 96% homologous, though they show only 43% identity with the S pigment. The high homology between the L and M pigments arises as a result of their particular genetic origin (see Genetic Structure). There are a number of conserved residues that have important structural and functional roles for the photopigment, a few of which are mentioned here. The ϵ-amino group of a lysine residue in the seventh transmembrane domain (position 296) forms a Schiff base linkage with the aldehyde portion of retinal, providing the linkage between the opsin and the 11-*cis*-retinal chromophore. A glutamate residue at position 113 serves as the counterion for this linkage. A proline residue at position 291 appears critical in maintaining the binding pocket for the chromophore. Two cysteine residues (positions 110 and 187) form a disulfide bond that is critical for proper folding of the photopigment (Karnik, S. S. *et al.*, 1988). Disruption of this disulfide bond results in a complete loss of function of the associated photopigment, leading to retinitis pigmentosa (RP) when observed in rhodopsin (Richards, J. E. *et al.*, 1995), and to a red/green color-vision deficiency when observed in either an L or an M pigment (Winderickx, J. *et al.*, 1992; Kazmi, M. A. *et al.*, 1997; Jagla, W. M. *et al.*, 2002; Neitz, M. *et al.*, 2004).

Mammalian photopigments display a number of posttranslational modifications – the formation of a Schiff base linkage between 11-*cis* retinal and the lysine residue at position 296 mentioned above is one such modification. In addition, the N-terminal contains a number of carbohydrate attachment sites for glycosylation. A common posttranslational modification among rhodopsins is palmitoylation of cysteine residues at positions 322 and 323 (Figure 3), which may affect structural and functional roles such as membrane localization, protein stabilization, and receptor turnover (Ablonczy, Z. *et al.*, 2006). This palmitoylation appears to be absent from the mammalian cone opsins (Ostrer, H. *et al.*, 1998; Ablonczy, Z. *et al.*, 2006), though the functional consequence of this difference between mammalian rod and cone pigments remains to be determined. Finally, there is the potential for phosphorylation of serine and threonine residues on the C-terminus of the pigment molecule. For rhodopsin, this occurs primarily at positions 338 and 343, but other sites (e.g., 334 and 336) may also be involved (Hurley, J. B. *et al.*, 1998; Maeda, T. *et al.*, 2003).

1.09.2.3 Genetic Structure

Among mammals, a separate gene encodes each of the opsins found in rods and cones. The structure and length of mammalian opsin genes differs between species (Yokoyama, S. and Yokoyama, R., 2000). In humans, the gene encoding rhodopsin is 5.0 kilobase (kb) long and found on chromosome 3, while the gene encoding the S opsin is located on chromosome 7 and is 3.2 kb long. The rhodopsin and S-opsin genes each have four introns and five exons (Figure 4). As a result of their autosomal location, humans normally have two copies of each of these genes. In contrast, the L/M gene(s) are located on the X-chromosome. While most mammals have only a single L/M gene on the X-chromosome, most Old World primates (including

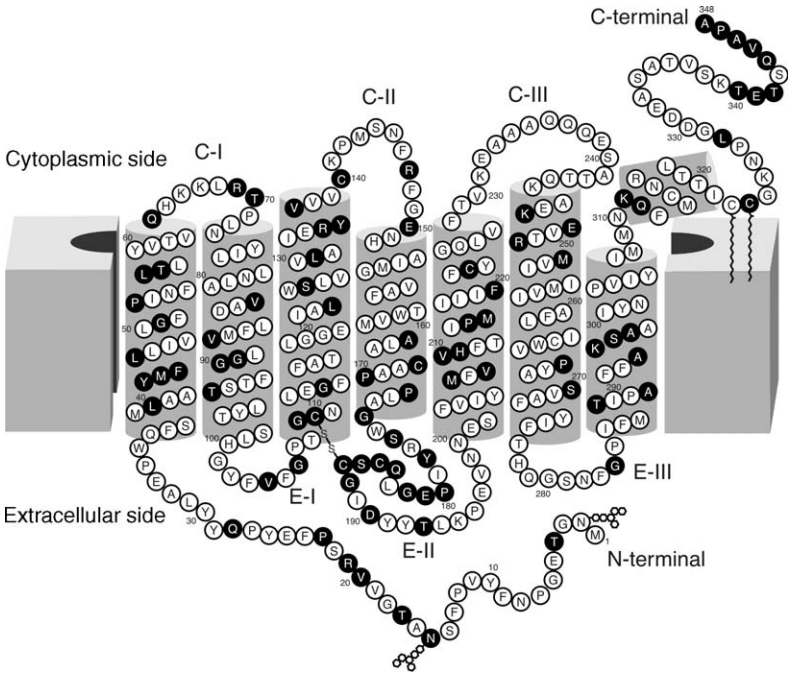

Figure 3 Two-dimensional model of human rhodopsin. Each circle represents a single amino acid, with 88 mutation sites identified by filled circles. Nearly every mutation has been associated with autosomal dominant retinitis pigmentosa (RP), while the others either cause congenital stationary night blindness (CSNB) or are believed to be benign. The α-helical transmembrane segments are connected by three cytoplasmic (interdiscal) and three extracellular (intradiscal) loops (indicated as C-I, E-1, etc.). The depicted secondary structure is based on the crystal structure reported by Palczewski, K., Kumasaka, T., Hori, T., Behnke, C. A., Motoshima, H., Fox, B. A., Letrong, I., Teller, D. C., Okada, T., Stenkamp, R. E., Yamamoto, M., and Miyano, M. 2000. Crystal structure of rhodopsin: A G-protein-coupled receptor. Science 289, 739–745 and is adapted from Stenkamp, R. E., Filipek, S., Driessen, C. A. G. G., Teller, D. C., and Palczewski, K. 2002. Crystal structure of rhodopsin: a template for cone visual pigments and other G protein-coupled receptors. Biochim. Biophys. Acta Biomembranes 1565, 168–182, with permission.

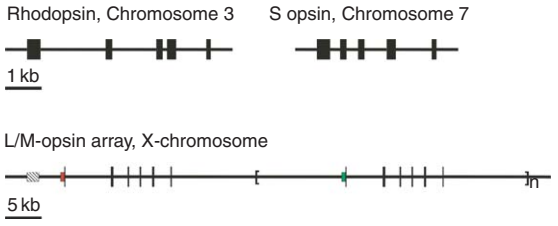

Figure 4 Schematic structure of the human opsin genes. Exons and introns are represented by vertical black boxes and horizontal lines, respectively. L and M genes reside in a head-to-tail tandem array, which is variable in gene number. The most common configuration among individuals with normal color vision is to have one L gene followed by one or more M genes. Each L or M gene is preceded by a proximal promoter (colored boxes), and the entire array has a single locus-control region (LCR) that is essential for the expression of genes from the array. Data on exon and intron lengths were taken from http://genome.ucsc.edu/cgi-bin/hgGateway (March 2006 build).

humans) possess both L and M genes. The physiological implications of having multiple pigments are covered below. In primates that have both the L and M genes on a single X-chromosome, they are located in a tandem array near the end of the long arm of the X-chromosome (Xq28) (Nathans, J. *et al.*, 1986b; Vollrath, D. *et al.*, 1988). This arrangement arose via a gene duplication event that is estimated to have occurred some 35 million years ago (Hunt, D. M. *et al.*, 1998). The selective expression of the L and M genes depends on a locus-control region (LCR) that is located about 3.5 kb upstream of the array (Wang, Y. *et al.*, 1992; Smallwood, P. M. *et al.*, 2002).

The L and M genes contain five introns each and six exons and are about 13.1 kb long (see Figure 4). Although the majority of humans have an intron 1 insert of about 2 kb in the L-pigment gene, about

35% of African-Americans lack this insert, while fewer than 1% of Caucasians have the shortened L-pigment gene (Jørgensen, A. L. *et al.*, 1990). There have been no reported phenotypic differences associated with having a shortened L-pigment gene. In individuals with normal color vision, it appears that the L gene is always the first gene in the X-chromosome tandem array. While there have been reports of individuals having L and M genes where the M gene is in the first position of the array, all had an accompanying color-vision deficiency due to other abnormalities in the array (Neitz, M. *et al.*, 2004; Ueyama, H. *et al.*, 2006).

As mentioned above, most mammals have only a single X-encoded photopigment gene. In some trichromatic primates, there is variability in the number of genes in this array. Among humans with normal color vision, the number of genes in the array varies from 2 (the minimum required to confer trichromacy) to as many as 9, with a mode of 3 (Drummond-Borg, M. *et al.*, 1989; Neitz, M. and Neitz, J., 1995; Neitz, M. *et al.*, 1995; Macke, J. P. and Nathans, J., 1997; Yamaguchi, T. *et al.*, 1997). Curiously, other trichromatic Old World primates show nowhere near this degree of variability in gene number (Onishi, A. *et al.*, 1999). The relevance of the variability in gene number for human color vision is not clear, especially given evidence suggesting that only the first two genes in the L/M array are significantly expressed (Hayashi, T. *et al.*, 1999).

The elucidation of the genetic basis for the mammalian photopigments has provided the opportunity to manipulate these genes so as to better understand the functional roles of the various pigments. For example, numerous rodent models expressing mutant rhodopsins have been used to examine the initial molecular mechanisms in human diseases involving analogous rhodopsin mutations (e.g., Hafezi, F. *et al.*, 2000; Jones, B. W. and Marc, R. E., 2005), while mice engineered to express a novel photopigment have been used to probe the evolutionary basis of color vision (Smallwood, P. M. *et al.*, 2003; Onishi, A. *et al.*, 2005; Jacobs, G. H. *et al.*, 2007).

1.09.3 Photopigment Function

The main business of the photoreceptor cells is to signal the capture of photons. As mentioned above, light serves as the ligand for the photopigments (GPCR), and absorption of light by the retinal chromophore causes an isomerization from the 11-*cis* to the all-*trans* form. The isomerization process is extraordinarily fast, occurring on a femtosecond time scale. Isomerization initiates a complex biochemical cascade that begins with conformational changes in the opsin protein that enable the associated G-protein (transducin) to bind to the cytoplasmic surface of the photopigment. This binding by the photopigment is regulated by discrete amino acids in the opsin portion of the pigment molecule. The end result of the subsequent steps in the cascade is a hyperpolarization of the cell in response to light. There are differences in some of the phototransduction proteins found in rods and cones, but the general process is the same for the two types of receptor (see Chapter Phototransduction in Rods and Cones for more detail). This section contrasts some of the functional properties of rods and cones.

1.09.3.1 Rod and Cone Specializations

Rod and cone photoreceptors have a number of important specializations that give them distinct functional properties. The primary advantage of having two classes of photoreceptor is to allow the visual system to function over a wide range of light intensities, about 11 orders of magnitude in the human eye. Rods are extremely sensitive – they are able to detect a single photon and thus work well at very low light intensities. Cones, on the other hand, are less sensitive and function best at higher light levels. Cones start to respond when they absorb light at a rate of about 3 photons/cone/s and continue to respond well for light intensities extending up to 1 000 000 photons per cone per second. In addition, cones respond more briskly to light, while rods have a more sluggish response. These physiological differences can be explained in part by the higher level of spontaneous activity in the cones; for example, L cones show about 10 000 times more frequent spontaneous isomerizations than do rods (Kefalov, V. *et al.*, 2003). The increased spontaneous activation in cones results in a high level of basal activity of the phototransduction components, thus reducing sensitivity while allowing a faster response recovery (Nikonov, S. *et al.*, 2000). Current evidence suggests that phototransduction cascade components downstream from the photopigment do not contribute significantly to the difference in rod versus cone sensitivity (Ma, J. *et al.*, 2001), though the issue is not entirely resolved. Studies on photoreceptor sensitivity have been done on various animal models (e.g., primate, African clawed frog, and tiger salamander), so it is likely that species differences have complicated our view

of rod and cone sensitivity. Moreover, there have been reports of differences in sensitivity between spectral subtypes of cone (Perry, R. J. and McNaughton, P. A., 1991; Makino, C. L. and Dodd, R. L., 1996), so variation in the opsin molecule itself may be contributing to the observed differences in sensitivity.

Another important difference between rods and cones is that at moderate light levels, rods reach a maximum response (saturate) and are thus unable to respond to continued increases in light intensity, while cones do not saturate under usual viewing conditions (though cones can be saturated with flash stimulation). The illumination levels at which rods saturate is quite low; for example, human rods are saturated under conditions of normal room illumination. This means that most of the time human vision is based on cone photoreceptors, which paradoxically comprise only 5% of the total number of photoreceptors in the human retina.

1.09.3.2 Metabolic Support of Photoreceptors

The photoreceptors of the human retina are the most metabolically active cells in the body. They rely heavily on the retinal pigment epithelium (RPE) for a great deal of their metabolic support. The RPE absorbs scattered light, transports metabolic byproducts from the subretinal space to the blood, delivers nutrients from the blood to the photoreceptors, and regenerates 11-*cis*-retinal (see Strauss, O., 2005 for a thorough review of the RPE). A normal rod cell sheds about 10% of its outer segment each day (Bok, D., 1985), and the RPE also performs the critical role of phagocytizing the shed photoreceptor material. The number of photoreceptors supported by a given RPE cell varies with retinal location – near the fovea as many as 15 cones are supported by one RPE cell, while in the periphery the total number of photoreceptors (rods + cones) supported by a single RPE cell may be as high as 40 or 50 (Snodderly, D. M. *et al.*, 2002). This topographical variation may have important consequences for the progression of various retinal degenerations. Recent advances in *in vivo* retinal imaging techniques (e.g., adaptive optics) make it possible to simultaneously image the cone and RPE mosaic in the living primate retina (Gray, D. C. *et al.*, 2006). These imaging techniques are likely to rapidly advance our understanding of the topographical relationship between the RPE/cone mosaics in normal and diseased retinas.

1.09.4 Diversity of Mammalian Photopigments

While mammalian photopigments have a number of structural and functional similarities, they are a diverse group of proteins. Of those pigments found in rods and cones, there is enormous variability in their spectral sensitivity. Recently, it has been discovered that photopigments exist in other cell types as well. In this section, we review what is known about the diversity among mammalian photopigments.

1.09.4.1 Spectral Tuning of Photopigments

As mentioned above, a common characteristic used to classify photopigments is the location of peak sensitivity (λ_{max}). Mammalian pigments have λ_{max} values ranging from about 360 to 565 nm, though all have an identical shape when plotted on a log-wavenumber axis. Since all mammalian photopigments employ the same chromophore (11-*cis*-retinal), the difference in λ_{max} between photopigments is attributed to the opsin portion of the photopigment. In particular, it is now known that a limited number of positions within the opsin molecule play major roles in spectrally tuning the pigment, a fact consistent with the observation that the λ_{max} values of vertebrate pigments tend to cluster at discrete spectral locations (Dartnall, H. J. A. and Lythgoe, J. N., 1965; Jacobs, G. H., 1998).

The chromophore 11-*cis*-retinal is joined to the opsin protein via a Schiff base linkage with a lysine residue at position 296 (human rhodopsin numbering) in the seventh transmembrane domain, while a glutamate at position 113 in the third transmembrane domain serves as the counterion to the protonated Schiff base. In solution, a protonated 11-*cis*-retinal Schiff base linkage absorbs maximally at about 440 nm. Deviations from this value are referred to as the opsin shift (Nakanishi, K. *et al.*, 1980) because the spectral shift is induced by the surrounding opsin protein. As described by Nathans, J. (1999), delocalization of the positive charge on the protonated Schiff base affects the spectral tuning of the pigment, with an increase in delocalization leading to a long-wavelength shift and a decrease in delocalization resulting in a shift toward the short wavelengths. This alteration of the charge distribution across the chromophore is accomplished through interactions between dipolar amino acid residues and the

chromophore (Kochendorfer, G. G. *et al.*, 1999; Lin, S. W. and Sakmar, T. P., 1999) and through a modulation of the interaction between the counterion (glutamate) and the protonated Schiff base.

Numerous amino acid residues within the opsin molecule have been implicated in spectral tuning of the mammalian cone photopigments. Among the L/M-cone pigments, five positions have been identified as major spectral tuning sites – 180, 197, 277, 285, and 308 (Yokoyama, S. and Radlwimmer, F. B., 1998). The S180A variants (mutants) are designated by the native amino acid residue and its position within the molecule followed by the substituted amino acid residue. For example, S180A refers to substitution of alanine for serine at position 180., H197Y, Y277F, T285A, and A308S substitutions shift the λ_{max} to shorter wavelengths by an estimated 7, 28, 7, 15, and 16 nm, respectively (Yokoyama, S. and Radlwimmer, F. B., 1999), although the magnitude of each individual substitution varies depending on the context. The tuning of S pigments is more complicated; at least nine positions within the opsin molecule are required to shift the absorption of rhodopsin from about 500 to 440 nm (Lin, S. W. *et al.*, 1988). Since the λ_{max} of the typical human S-cone pigment is about 420 nm, additional sites must also be involved. Additional sites have been shown to function synergistically to shift the λ_{max} to even shorter wavelengths, accounting for the observed λ_{max} of mouse ultraviolet (UV) pigments (Yokoyama, S. and Shi, Y., 2000). It should be noted that these *in vitro* studies can provide information about the effect of individual amino acid substitutions, but by themselves they offer only limited insight into the evolutionary origin of these changes.

Given their role in human trichromatic color vision, the L- and M-cone pigments have received particular attention. The number of amino acid differences between the human L- and M-cone pigments is highly variable, ranging from a minimum of 8 to a maximum of 18 (mode = 14) (Figure 5), though positions 277 and 285 account for the majority of the

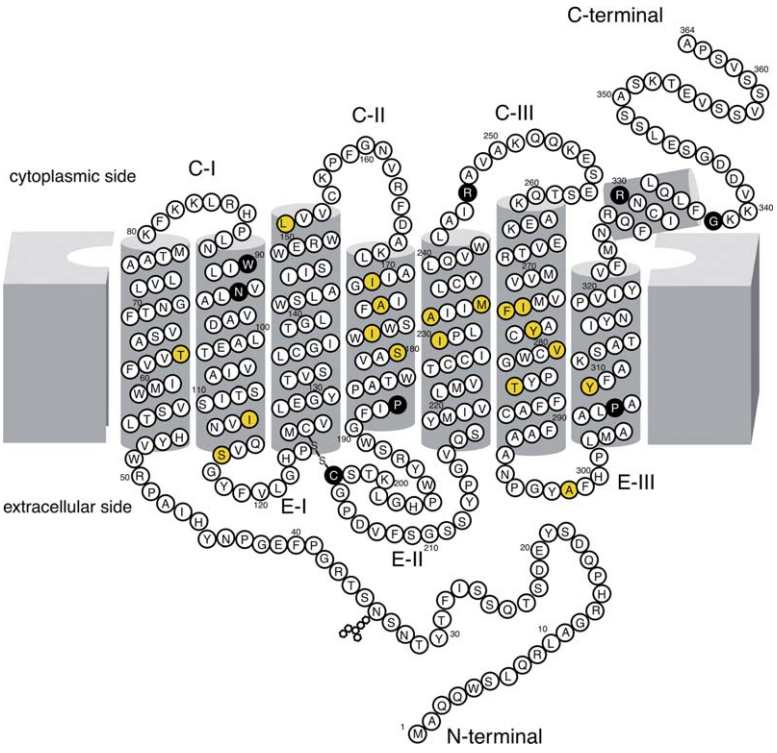

Figure 5 Two-dimensional model of the human L and M opsins. Each circle represents a single amino acid, with mutations associated with the loss of L- or M-pigment function shown as filled black circles. Filled yellow circles represent the dimorphic sites that can differ between the L and M pigments. A number of these sites have been shown to be involved in the spectral tuning of the pigments (see text). The amino acid identities at all 18 dimorphic sites are those of the presumed primordial L opsin (Deeb, S. S. *et al.*, 1994). Adapted from Stenkamp, R. E., Filipek, S., Driessen, C. A. G. G., Teller, D. C., and Palczewski, K. 2002. Crystal structure of rhodopsin: a template for cone visual pigments and other G protein-coupled receptors. Biochim. Biophys. Acta Biomembranes 1565, 168–182, with permission.

30 nm difference between L- and M-pigment λ_{max} (Neitz, M. *et al.*, 1991; Asenjo, A. B. *et al.*, 1994). In fact, with rare exception, positions 274, 275, 277, 279, 285, 298, and 309 all covary. That is, these sites vary between but not within the L and M photopigments, and thus the identity of these amino acid positions can be used to fairly reliably classify human L/M pigments as either L or M. The remaining 11 polymorphic positions show significant variation within the L- and M-pigment classes (Figure 6), and there is corresponding variability in the λ_{max} of human L- and M-cone pigments. Mutagenesis studies revealed that of these 11 sites, only positions 116, 180, 230, and 233 significantly affect the spectral tuning of the pigment (Asenjo, A. B. *et al.*, 1994). It thus becomes possible, given the sequence of a particular L or M pigment, to deduce its λ_{max}. Measurement of the spectral sensitivity of human dichromats possessing only a single L or M pigment, combined with analyses of their L- or M-pigment genes, suggests that, at least in humans, this practice is reliable (Sharpe, L. T. *et al.*, 1998; Carroll, J. *et al.*, 2002).

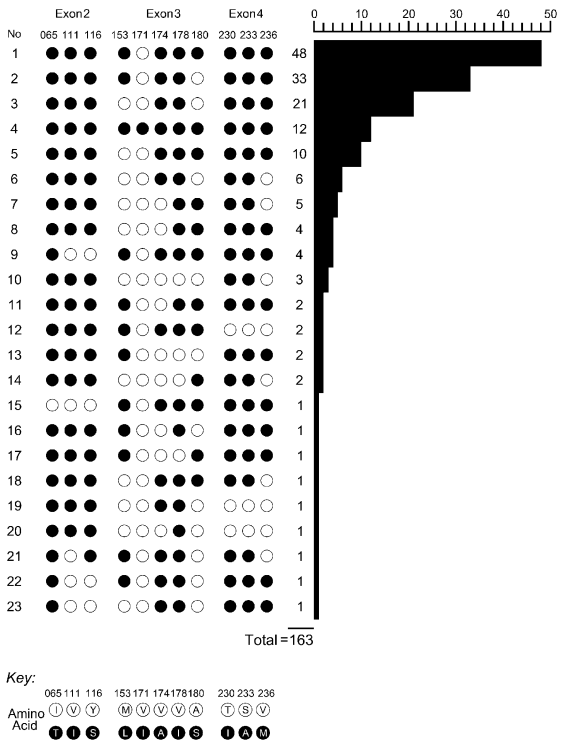

Figure 6 Variability in the human L-cone pigment observed among 163 males with normal color vision. Only the polymorphisms encoded by exons 2–4 vary within L and M pigments; that is, the identities of the seven polymorphic sites encoded by exon 5 covary and are thus used to classify a pigment as L or M. The key at the bottom indicates the amino acid identity of the polymorphic sites for the primordial M (top row) and L (bottom row) pigment. Accordingly, in the histogram, the filled circles represent primordial L-pigment amino acids, while open circles indicate primordial M-pigment amino acids. There has been significant intermixing of the L and M genes, resulting in this widespread variability in the L-cone pigment; for example, the presumed primordial L pigment is only the fourth most common variant. This degree of polymorphism among the L/M pigments appears to be unique to humans. Courtesy of J. Neitz and M. Neitz (unpublished data).

The spectral position of mammalian (indeed, all vertebrates) pigments appears to be nonrandom. While the clustering is a consequence of there being discrete amino acid positions that tune the spectrum, there is evidence that pigment positioning may also be driven by evolutionary considerations. For example, the λ_{max} of rhodopsin in the Mexican cavefish is shifted to longer wavelengths, and it has been suggested that this may reflect the visual requirements of life in a shallow freshwater environment (Yokoyama, S., 1997). Among the cottoid fish of Lake Baikal, as the depth of habitat increases, the λ_{max} of the pigments tend to decrease in line with the availability of ambient light at progressively deeper locations (Bowmaker, J. K. and Hunt, D. M., 2006) Likewise, the inferred rod pigment λ_{max} of the deep-diving elephant seal may be similarly adapted for vision in a marine environment, also being shifted toward shorter wavelengths (Levenson, D. H. *et al.*, 2006). Although these examples would seem to support the general view that photopigment positioning can be tuned in accord with environmental lighting, there is equally strong evidence to suggest that establishing such linkages will not be straightforward. For example, among the deep-diving pinnipeds, elephant seals may be unusual since many other species sharing these same habitats have rod pigments with the same spectral positioning as terrestrial mammals (Levenson, D. H. *et al.*, 2006). It seems likely that a much deeper understanding of the visual ecology of various mammalian lineages will be required in order to draw any tight connections between photic environments and photopigment positioning.

1.09.4.2 Nonrod, Noncone Opsins

Mammalian photopigments are not just restricted to the photoreceptor cells in the retina; in fact, they are not even restricted to retina. In recent years, a number of nonrod, noncone photopigments have been discovered (e.g., neuropsin, encephalopsin, RPE retinal G-protein-coupled receptor (RGR), peropsin, and melanopsin) (for recent reviews see

Foster, R. G. and Hankins, M. W., 2002; Kumbalasiri, T. and Provencio, T., 2005). Among vision scientists, melanopsin has received a great deal of attention as it has been linked to the process of circadian photoentrainment. Recently, it has been shown that melanopsin expression is restricted to a small subset of retinal ganglion cells (Hattar, S. *et al.*, 2002; Sollars, P. J. *et al.*, 2003). Indeed, these melanopsin-containing ganglion cells are intrinsically photosensitive (thus called ipRGCs), and they have been shown to play a role in activities like circadian photoentrainment, the pupillary light reflex, and regulation of the melatonin biosynthetic pathway. The response of melanopsin is much slower than that of the rod or cone opsins, so it is unlikely that these cells participate in most visual functions. There is a plethora of behavioral, physiological, and molecular data regarding the role of melanopsin, see Chapter Melanopsin Cells for more detail.

1.09.4.3 Evolution of Mammalian Photopigments

Over the past two decades, opsin gene sequences have been determined for many different species. Comparisons of these sequences can then be used to derive deductions about the evolution of photopigments. A consensus emerging from such comparisons is that all vertebrate photopigments fall into five paralogous groups (Hisatomi, O. and Tokunaga, F., 2002; Yokoyama, S., 2002). Figure 7 shows a vertebrate opsin family tree illustrated for a small sample of representative vertebrate species. Four of the opsin gene families (designated as LWS, Rh2, SWS2, and SWS1) specify photopigments typically expressed in cones, while the Rh1 derivatives are rod photopigments. An important insight emerging from this work is that rod pigments evolved only after all four of the cone pigment gene families were in place. The relative timing of the emergence of rod and cone photopigments is taken to imply that a capacity for daylight vision, including very likely some color vision, has been present throughout much of vertebrate history and that rod-mediated vision is a relatively more recent invention, perhaps arising coincident with the appearance of jawed vertebrates (Collin, S. P. *et al.*, 2003).

As illustrated in Figure 7, representatives from all four classes of cone opsin genes are present in some contemporary birds, fishes, and reptiles. Note however that the lone representative mammal in Figure 7

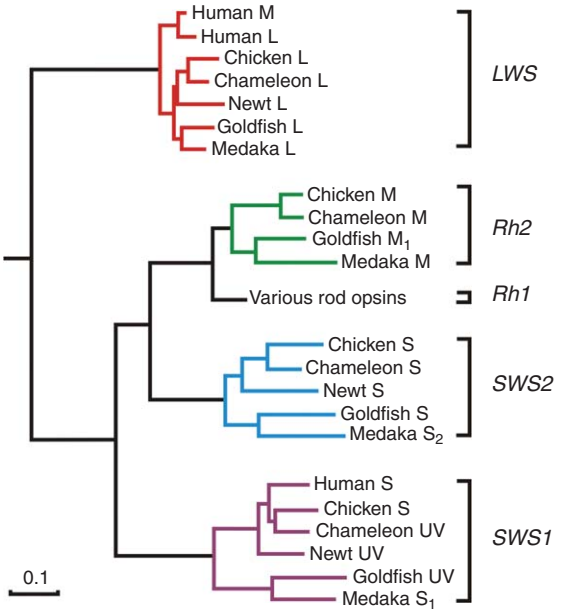

Figure 7 Phylogenetic relationship of some vertebrate opsins. The proposed relationships are inferred from comparison of published opsin gene sequences using the neighbor-joining method. Shown here are pigments from four cone opsin gene families and a single rod opsin gene family. Source: Jacobs, G. H. and Rowe, M. P. 2004. Evolution of vertebrate colour vision. Clin. Exp. Optom. 87, 206–216; reproduced with permission from Optometrists Association Australia.

(humans) draws cone pigments from only two of the four gene families (LWS and SWS1). That exclusivity seems true for all eutherian mammals. Early mammals are believed to have been strongly nocturnal, and it seems plausible that this phase of our photic history stimulated a number of alterations in mammalian retinas including, (a) average increases in rod/cone ratios, (b) loss of colored oil droplets from photoreceptors that remain characteristic of many other contemporary vertebrates, and (c) the disappearance of representative cone pigments from the Rh2 and SWS2 gene families (Jacobs, G. H. and Rowe, M. P., 2004). The latter change would imply that our early mammalian ancestors were limited to only two types of cone pigment, one absorbing maximally in the short wavelengths, the other in the middle to long wavelengths. Based on a comparison of the amino acid sites that are believed important for spectral tuning, the λ_{max} of the original mammalian LWS pigment has been inferred to have been at about 530 nm (Yokoyama, S. and Radlwimmer, F. B., 1999). From that point, subsequent divergences have spread the λ_{max} of mammalian pigments from this gene family across the middle- to long-wavelength

portion of the spectrum so as to yield values ranging from about 493 to 565 nm. Among early mammals, the short-wavelength pigment derived from the SWS1 gene family probably had maximum absorbance in the UV (Hunt, D. M. *et al.*, 2004). That spectral position has been retained in some contemporary mammals, but in many others, gene alterations have yielded pigments that are peak shifted toward the longer wavelengths. The result is that pigments found in contemporary mammals that are specified by genes in the SWS1 family span a range of λ_{max} values from about 360 to 445 nm.

Two groups of contemporary mammals differ significantly from this standard picture. First, many primate species have acquired a second LWS-based photopigment through processes detailed below, thus giving them a total of three types of cone pigment. Additionally, recent evidence suggests that some Australian marsupials have retained cone pigment representation from the Rh2 opsin gene family and so, like many primates, they too have a total of three types of cone pigment (Arrese, C. A. *et al.*, 2002). Why these marsupials have retained their Rh2 pigments while all other mammals have abandoned them is currently unknown.

1.09.5 Photopigments and Mammalian Color Vision

Except under limited circumstances, color vision reflects the operation of cones, and thus the emergence of color vision must be ultimately linked to the absorption of light by cone photopigments. Animals are said to have color vision if they can discriminate between lights of different spectral composition irrespective of their relative intensities (Jacobs, G. H., 1993; Kelber, A. *et al.*, 2003). Photoreceptors respond univariantly, providing a signal proportional to the number of photons captured by the resident pigment (thereby confounding wavelength and intensity), and thus an individual with only a single type of photoreceptor lacks color vision (Rushton, W. A. H., 1972). Such animals are classified as monochromatic. The dimensionality of color vision can be formally established through color matching, that is, determining by psychophysical measurement the number of lights of fixed spectral composition (so-called primaries), each independently adjustable in intensity, which are required to match in appearance any spectral light. If two primaries are required, the animal is said to be dichromatic; three confirms trichromacy, etc. The number of spectrally unique receptor types is compulsively linked to color-vision dimensionality in that there cannot be fewer receptor types than there are numbers of color-vision dimensions.

In light of this linkage between color vision and receptor types, knowledge about the number of cone photopigments present in any animal is frequently used to infer facts about color vision, for example, animals found to have two types of cone opsin genes are often described in the literature as being dichromatic. This is an obviously attractive strategy because it is almost always much easier to gain information about photopigments (or their genes) than it is to conduct direct studies of color-vision behavior. There are however some important additional assumptions that are required to make the inferential step between cone photopigment complement and color vision. First, the nervous system of the animal must be organized to allow signals from different cone types to be contrasted. Fortunately, the retinal pathways that permit such signal comparisons in mammalian retinas are largely conserved across the order (see Chapter Decomposing a Cone's Output (Parallel Processing)) and that commonality makes the inferential leap from the number of cone pigments to the dimensionality of color vision somewhat less risky. A second requirement is that the various cone pigment types have to be (at least to some extent) individually expressed in photoreceptors. The issue of photopigment expression is considered below. Finally, most procedures that allow the identification of the cone pigment types do not provide information about the relative numbers of cones containing each of the pigment types or about their distribution across the photoreceptor mosaic. Both of these features can greatly impact the quality of color vision, even as they may be without effect on the dimensionality of color vision. Clearly, learning the identity of the cone pigments in any given species is an important first step toward understanding its color-vision capacity, but it provides an incomplete picture.

1.09.5.1 Photopigment Expression

Photoreceptors respond univariantly. One consequence of this is that the expression of multiple cone pigments in each receptor will broaden the absorption spectrum for that receptor but will not allow the initiation of signals needed to support color vision. Consequently, the evolution of color

vision requires both the addition of spectrally unique photopigments and a mechanism for selective expression of the different types of photopigment. As mentioned above, among trichromatic mammals, the proximate mechanism that provides selective expression is an LCR located 3.5 kb upstream of the L/M-opsin gene array (see Figure 4). The LCR is presumed to act on the opsin gene promoter to activate gene transcription (Nathans, J. *et al.*, 1989; Wang, Y. *et al.*, 1992; Nathans, J. 1999; Smallwood, P. M. *et al.*, 2002).

Psychophysical studies of human color vision have long made clear that cone pigments must be selectively expressed, and, eventually, direct measurements made on primate cones provided evidence that, indeed, each cone contains only a single type of cone pigment (Dartnall, H. J. A. *et al.*, 1983; Schnapf, J. L. *et al.*, 1987). In recent years, however, it has been learned that the idea that any given cone must contain only a single type of photopigment does not hold for all mammals (for a recent review of this topic see Lukáts, A. *et al.*, 2005). So far, it appears that most of the species featuring cone pigment coexpression are rodents, but more may well be found as appropriate measurements are extended to include additional species. Interestingly, it has been shown that for some species (including primates), the coexpression profile in adulthood differs from that observed during development (Szél, Á. *et al.*, 1994; Xiao, M. and Hendrickson, A., 2000). The functional significance of this remains to be elucidated, although one possibility is that it is a remnant of the molecular processes of cone differentiation. Furthermore, in many species exhibiting coexpression in the adult retina, it appears to be incomplete in that not every cone coexpresses the two pigments to the same extent. A prominent example of such an arrangement is seen in the retina of the house mouse which features a topographic distribution pattern of the two pigment types, with M pigment more strongly expressed in the dorsal retina and UV pigment showing the reverse pattern (Applebury, M. L. *et al.*, 2000). Even though pigment coexpression is common in this retina, apparently some cones do express only a single pigment type (Haverkamp, S. *et al.*, 2005). The consequences that photopigment coexpression may have for vision are not well studied, but at least in the mouse, partial cone pigment coexpression does not eliminate the possibility for some limited color vision (Jacobs, G. H. *et al.*, 2004).

1.09.5.2 The Mammalian Theme: Two Types of Cone Pigment

Only two (SWS1 and LWS) of the four families of vertebrate cone opsin genes appear to have representation in eutherian mammals. A consequence is that with the exception of some primates, a group considered separately below, all other mammals express no more than two types of cone photopigment. One of these has peak sensitivity in the short wavelengths; the other is maximally sensitive to lights from the middle and long wavelengths (see Figure 2(a)). This provides the photopigment basis for dichromatic color vision. That capacity is believed to be widespread among mammals, although the reader should be cautioned that direct tests of color vision have been made on only a relatively small proportion of the some 4500 species of mammal. Details regarding the photopigment complements and color vision in the mammals that have been studied to date are summarized in a number of recent review papers which may be consulted for information about particular species (Jacobs, G. H., 1993; Yokoyama, S. and Radlwimmer, F. B., 1998; Ahnelt, P. K. and Kolb, H., 2000; Kelber, A. *et al.*, 2003; Peichl, L., 2005). We offer here a few summary observations on this photopigment theme.

Although the presence of two cone pigments is common in mammals, there are significant variations in the spectral positioning of these pigments. There are few generalizations to be gained from examination of the spectral placement of mammalian cone pigments, and likely most have exceptions. Most carnivores and ungulates studied so far have L/M pigments with λ_{max} values > 530 nm, while the corresponding pigments of most rodents have λ_{max} shorter than that value. The L/M pigments of marine mammals follow the pattern of terrestrial carnivores, while lagomorph L/M pigments seem similar to the rodents. Inferences drawn from studies of cone opsin genes suggest that some of the Chiroptera also have L/M-cone pigments positioned toward the longer wavelengths (Wang, D. *et al.*, 2004). Mammalian SWS1 pigments fall into two categories. A number of rodent species, including common laboratory animals such as mice and rats, have a UV pigment with a λ_{max} of about 360 nm (Jacobs, G. H. *et al.*, 1991). In all other mammalian groups, with the possible exception of some bats (Wang, D. *et al.*, 2004), the SWS1 pigments have been shifted into the visible, with associated λ_{max} values spread across the range from about 420 to

445 nm. Interestingly, some rodent species also have pigments in this latter interval.

As described above, the proximate reason for the variations in the spectral positioning of mammalian cone pigments rests on variations in a limited number of amino acid tuning sites in the opsin molecules. It is natural to assume that there are also adaptive reasons why particular animals or groups of animals have the pigments they do. As we noted above, if there are such reasons, they so far have defied easy understanding. Thus, mammals that occupy widely different photic habitats and natural histories often share their pigment positions in common. For example, the L/M pigment found in the deep-diving elephant seal has the same spectral absorption as the L/M pigments of domestic cats and goats (Levenson, D. H. *et al.*, 2006). It is not obvious how the presence of this same photopigment could be matched to seemingly disparate visual demands of all of these mammals. The absence of clear correlations between visual behavior and pigment positioning may obviously reflect a lack of a deep understanding of the visual ecology of these species, but among some invertebrates, phylogenetic relatedness better predicts pigment complement than does visual ecology (Briscoe, A. D. and Chittka, L., 2001), and that may well be the case here as well. Finally, quite beyond the issue of cone pigment positioning, there are significant variations across mammals in the relative numbers of cones and their retinal topography (Ahnelt, P. K. and Kolb, H., 2000). These factors will greatly influence the character of the visual message available to the downstream visual structures; thus, the mere fact that many mammals have two types of cone pigment provides only a relatively weak link to understanding how they see.

1.09.5.3 Evolutionary Loss of Mammalian S-Cone Pigments

A few years ago, the retinas of two types of primates (*Aotus*, the owl monkey and *Otolemur*, the bush baby) were shown to lack a population of functional S cones (Jacobs, G. H. *et al.*, 1996b). The absence of these cones was traced to the presence of deleterious mutational changes in the S-cone opsin genes that obviate pigment expression. Since that time, a variety of mammals have been shown to share a similar loss. The list of species so afflicted includes some prosimian primates, a number of rodents, some species from the family Procyonidae (raccoons, etc.), and apparently all marine mammals from the families Cetacea (dolphins and whales) and Pinnipedia (seals) (for complete listings see Peichl, L. and Moutairou, K., 1998; Peichl, L. *et al.*, 2001; Ahnelt, P. *et al.*; 2003; Levenson, D. H. and Dizon, A. 2003; Kawamura, S. and Kubotera, N., 2004; Levenson, D. H. *et al.*, 2006). There are probably still other species (so far, undetected) showing a similar loss.

As discussed below, some humans also lack S cones under circumstances that are traceable to mutational changes in their S-cone opsin genes. There is, however, an important difference between the losses of S cones in humans and in these other mammals – whereas the absence of S cones is rare among humans, S-cone loss is believed to be characteristic of all individuals in these other species. Although a species-wide loss of S-cone pigment could reflect the evolutionary occurrence of a neutral event, an alternative interpretation is that this loss represents an adaptive change that somehow increased the fitness of these animals.

Beyond the general thought that the absence of S cones might be adaptive, little progress has been made in understanding the circumstances surrounding this loss. In most mammalian retinas, S cones comprise only a very small proportion of all the cones. Partly because of that, the presence of S cones does not substantially increase an animal's ability to capture photons. Rather, because mammalian retinas contain a conserved neural pathway that allows for the comparison of signals from S cones and L/M cones, the presence of S cones provides information that facilitates the extraction of a dimension of color vision. The absence of S cones thus reduces normally dichromatic mammals to monochromacy.

It is not easy to see how abandoning an apparently low-cost color-vision capacity could prove adaptive. The first mammals found to lack S cones were nocturnal, and since color vision is only modestly useful under low-light conditions, it initially seemed possible that nocturnality and the loss of S cones might be linked (Jacobs, G. H. *et al.*, 1996b). That linkage now seems less certain as some additional mammals found to lack S cones are not strictly nocturnal; for example, whereas many species of *Aotus* monkey are strongly nocturnal at least one genus is cathemeral (i.e., behaviorally active under strongly photopic as well as scotopic conditions), yet all show mutational loss of S-cone opsin genes (Levenson, D. H. *et al.*, in press). Conversely, some very stringently nocturnal species (e.g., the tarsier – Hendrickson, A. *et al.*, 2000)

maintain a viable population of S cones. In sum, the loss of S cones triggered by opsin gene mutation represents a significant variation on the mammalian cone pigment theme. At the same time, the total extent of this loss and its evolutionary explanation remain to be determined.

1.09.5.4 Primate Cone Pigments and Color Vision

The idea that normal human color vision is trichromatic dates from the seventeenth century (Mollon, J. D., 2003), and by the early twentieth century, it had become clear that some nonhuman primate taxa share this capacity (Grether, W. F., 1939). Trichromacy was initially thought to reflect the physical properties of light, and it was not until the turn of the nineteenth century that the physiological basis of trichromacy was realized. This connection between primate trichromacy and the retinal presence of three classes of cone pigment was conclusively established with the first reports of direct measurements of both human and nonhuman primate cone pigments (Brown, P. K. and Wald, G., 1963; Marks, W. B. *et al.*, 1964). Subsequently, and particularly over the past two decades, much has been learned about the distribution and nature of primate color vision, its linkage to the cone pigments and to opsin genetics, and the evolution of these capacities. A brief summary of these issues follows.

As far as we now know, all catarrhine primates (Old World monkeys, apes, and humans) effectively share in common their acute trichromatic color-vision capacities (Jacobs, G. H. and Deegan, J. F. II, 1999). The reason why this is the case is that all members of this lineage have effectively the same cone photopigment complements (see Figure 2(b)) specified by X-chromosome (L/M pigments) and autosomal (S pigment) opsin genes, and they all share important organizational features of the afferent visual system. In the face of this commonality, an intriguing difference among the catarrhines is that polymorphic variations in the L/M-opsin genes are relatively common among humans (e.g., see Figure 6), resulting in the much-studied phenotypic variations in human color vision. Analogous polymorphisms are very rare among the nonhuman catarrhines; for example, only three of a sample of over 3000 macaque monkeys showed evidence for such variation (Onishi, A. *et al.*, 1999), an incidence that is vastly lower than that documented for Western European human populations. This difference has sometimes been explained as reflecting variations in the stringency of selective pressures against defective color vision for humans and other catarrhines; moreover, it could also reflect differences in the physical nature of the X-chromosome opsin gene arrays of these primates (Jacobs, G. H. and Williams, G. A., 2001).

The platyrrhine (New World) monkeys have been the focus of much attention because, unlike the catarrhines, cone pigment and color-vision polymorphism is rampant among New World monkeys (see Jacobs, G. H., in press for a review). Indeed, with the exceptions of only two genera, all platyrrhine monkeys have polymorphic color vision. The polymorphism is such that among the members of any given species, both dichromatic and trichromatic individuals are found with subvarieties in each of these dimensional categories. In the majority of such polymorphic species, six distinct color-vision phenotypes occur, three dichromatic types and three trichromatic types. These color-vision variations directly reflect polymorphisms in the X-chromosome opsin genes and the cone pigments they encode. An important feature of these polymorphisms, and an early key to their understanding, is that although female monkeys may be either trichromatic or dichromatic, all males are dichromats. That fact pointed to a fundamental difference between the X-chromosome opsin genes of catarrhines and platyrrhine primates. As described above, in catarrhines, the L- and M-opsin genes are situated in tandem array on the X-chromosome. By contrast, platyrrhines have only a single X-chromosome opsin gene, with allelic versions of this gene specifying different L and M pigments. A consequence is that males perforce have only a single L/M pigment and dichromatic color vision. Homozygous females have pigment complements like the males, but heterozygous females, through the agency of X-chromosome inactivation, have a receptor mosaic that features both L- and M-cone types, and that arrangement supports a trichromatic color-vision capacity.

A central question in the evolution of primate color vision has been whether the addition of a new L/M-pigment type suffices to immediately yield a new dimension of color vision, or whether subsequent nervous system reorganization would be required. A recent study involving a knock-in mouse designed to mimic the polymorphic photopigment arrangement seen in platyrrhine monkeys shows that even the murine visual system is sufficiently plastic that new color vision can emerge

from the simple addition of a new L/M pigment (Jacobs, G. H. *et al.*, 2007). This result supports the view that the addition of a new pigment in our primate ancestors probably immediately yielded new color vision and, with it, the benefits that accrue to such capacity.

There are a number of well-described variations on the polymorphic theme of platyrrhine color vision (Jacobs, G. H., in press). First, although all the platyrrhine L/M pigments have λ_{max} falling in the range from 530 to 560 nm, different sets of these pigments characterize different phenotypic subgroups. Second, although a total of three polymorphic L/M pigments are most common, some genera may have only two such pigment types, while one species is believed to harbor a total of five polymorphic L/M pigments. Third, as noted above, one genus of New World monkey (*Aotus*) features a mutational change in the S-opsin gene that reduces the cone pigment complement to one type, thus obviating the possibility of any color vision. Finally, and perhaps most surprising, the monkeys of one genus, *Alouatta* (the howler monkeys), resemble catarrhine primates in having both L- and M-opsin genes on their X-chromosome. This arrangement presumably arose from a gene duplication, although the duplication event in the howler monkey is distinct from that which occurred in the catarrhines as it includes the LCR in the duplicated segment. It is unclear how the presence of two LCRs affects the relative expression of the L and M genes. Electroretinogram (ERG) data does demonstrate the presence of functional L and M photopigments in howler monkeys setting the stage for all individuals to express two types of L/M pigment and, potentially, achieve trichromatic color vision (Jacobs, G. H. *et al.*, 1996a).

Relatively less is known about cone pigments and their visual concomitants in the third group of primates, the more primitive strepsirrhines. Based mainly on inferences drawn from cone opsin genes, three patterns can be discerned (Jacobs, G. H., 1996; Tan, Y. and Li, W.-H., 1999; Kawamura, S. and Kubotera, N., 2004). As described above, some species have S-cone opsin pseudogenes and apparently lack any L/M polymorphism and so, as is the case with *Aotus*, these primates also lack color vision. Another group of strepsirrhines, among which the ring-tailed lemur is a good example (Jacobs, G. H. and Deegan II, J. F., 2003), follows the standard mammalian pattern in having a functional S-cone pigment and a single type of L/M pigment providing them with the basis for dichromatic color vision. Finally, some (seemingly limited) number of diurnal strepsirrhines resemble the platyrrhines in having polymorphism in a single L/M-opsin gene so that heterozygous females have two types of L/M pigment and, potentially, trichromatic color vision while the males are uniformly dichromatic.

In recent years, comparative examinations of primate opsin genes have provided the basis for numerous discussions about the evolution of the primate cone pigments (see, e.g., Nathans, J. 1999; Surridge, A. K. *et al.*, 2003; Hunt, D. M. *et al.*, 2005). Although there is agreement on some issues, there is still considerable ambiguity concerning many of the details. Because all catarrhines share in common two highly homologous X-chromosome opsin genes, the step from the normal mammalian pattern (a single X-chromosome opsin gene) to the catarrhine norm involved a gene duplication event that must have occurred near the base of the catarrhine radiation, estimated at 30–35 million years ago (Nathans, J. *et al.*, 1986b), with the platyrrhine/catarrhine divergence dated as occurring before catarrhine gene duplication. X-chromosome opsin gene duplication also must have occurred in the ancestors of the only routinely trichromatic platyrrhine, the howler monkeys. However, comparative examination of the structure of the opsin gene arrays (see above) indicates that the duplication in howler monkeys occurred as an independent event at a time much later than the catarrhine duplication (Hunt, D. M. *et al.*, 1998).

The origins of the L/M-cone pigment polymorphisms remain uncertain. The genetic divergence between the L/M alleles of New World monkeys is considerably smaller than the divergence between the L/M genes of the catarrhines. This would suggest the platyrrhine polymorphisms arose after the catarrhine duplication event, but it has been noted that the process of gene conversion can obscure ancestral differences, and in such cases sequence comparisons can prove inconclusive (Hunt, D. M. *et al.*, 1998). Complicating the issue further is the recent discovery that some strepsirrhine species also feature L/M-gene polymorphisms. One interpretation of this latter discovery is that polymorphism may have been present before the emergence of catarrhines/platyrrhine lineages, perhaps arising relatively early in primate history. However, these events are ultimately resolved; the modern understanding of the linkages between primate opsin genes, cone pigments, and color vision can provide a unique window into our primate past.

1.09.6 Role of Photopigments in Human Retinal Disease

A well-studied feature of human photopigments is how small perturbations in photopigment structure can lead to visual loss. Two examples of this are the relationship between rhodopsin mutations and RP, and the relationship between disruptions in the cone opsins and color blindness.

1.09.6.1 Rhodopsin-Based Disorders

Due in part to its complexity, the human retina is extremely susceptible to disease with degenerations triggered by a variety of environmental and genetic insults. The pathway to blindness in hereditary retinal degenerations originates primarily from mutations in the genes encoding photoreceptor and RPE proteins. One of the most studied of the hereditary retinal degenerations involves rhodopsin. Rhodopsin defects are a common perpetrator of retinal disease accounting for nearly 30% of all cases of RP, while, in total, it is estimated that these cases represent 15% of all hereditary retinal degenerations. There are over 130 distinct rhodopsin mutants involving at least 88 sites within the molecule (data compiled from Zhang, F. *et al.*, 1998; Dryja, T. P. *et al.*, 2000; Sohocki, M. M. *et al.*, 2001; Horn, F. *et al.*, 2003; Stone, E. M., 2003; Schuster, A. *et al.*, 2005; Neidhardt, J. *et al.*, 2006; Retina International 2006; Sullivan, L. S. *et al.*, 2006). With rare exception (e.g., Macke, J. P. *et al.*, 1993; Dryja, T. P. *et al.*, 2000), each of these mutations has been associated with either RP or the condition called congenital stationary night blindness (CSNB). The mutation sites in rhodopsin that are currently known are shown in Figure 3.

The initial cellular mechanisms that enable a mutation in the rhodopsin molecule to lead to complete blindness vary. For example, the P23H mutation has been shown to cause misfolding and retention of the opsin in the endoplasmic reticulum, while mutations near the C-terminal region result in a properly folded opsin that is not then correctly transported to the outer segment. The different mutations have been classified according to their specific biochemical properties, though a number of mutants remain unclassified (see Mendes, H. F. *et al.*, 2005 for a detailed review). The fact that each of these mutations leads to the eventual loss of rod cells emphasizes the critical role of rhodopsin in maintaining cell viability. Moreover, in rhodopsin-knockout mice (rho −/−), rod outer segments fail to develop, suggesting a structural role for rhodopsin (Humphries, M. M. *et al.*, 1997). Indeed, Kumar J. P. and Ready D. F. (1995) have shown that rhodopsin-null alleles in *Drosophila* induce structural abnormalities well before those that are induced by mutants linked to adult degeneration, consistent with the idea that besides its role in phototransduction, rhodopsin is critical in the initial development of the intricate photoreceptor structure.

1.09.6.2 Cone Pigment-Based Disorders

As we have described, the majority of mammals have dichromatic color vision. Among trichromatic species like humans, individuals that have regressed from this norm are commonly called color blind. The most frequent forms of color blindness are inherited, and these most often result from disruptions in the genes encoding the cone photopigments. Usually, it is the absence of one of the three photopigment genes or a mutation in one of these genes that results in a nonfunctional photopigment, but there is one other form of inherited color blindness (called achromatopsia or rod monochromacy) that results from a defect in the components of the cone phototransduction cascade. For an extensive review on this latter disorder, see Hess R. F. *et al.* (1990). Here, we summarize what is known about the photopigment-based color-vision defects.

1.09.6.2.1 Red-green color-vision defects

Two main causes of inherited red-green color-vision deficiency have been identified. The most common cause is rearrangement of the L/M genes resulting either in the deletion of all but one visual pigment gene or in the production of a gene array in which the first two genes both encode a pigment of the same spectral class (Nathans, J. *et al.*, 1986a; Deeb, S. S. *et al.*, 1992; Jagla, W. M. *et al.*, 2002; Ueyama, H. *et al.*, 2003; Neitz, M. *et al.*, 2004). The second general cause is the introduction of an inactivating mutation in either the first or second gene in the array. The most prevalent inactivating mutation results in the substitution of arginine for cysteine at position 203 (C203R) in the L/M pigment (Winderickx, J. *et al.*, 1992; Bollinger, K. *et al.*, 2001; Neitz, M. *et al.*, 2004). Cysteine 203 forms an essential disulfide bond that is highly conserved among GPCRs (Sakmar, T. P., 2002). This mutation was first observed in blue cone monochromacy (BCM) (Nathans, J. *et al.*, 1989) where it was

shown to directly disrupt photopigment function (Kazmi, M. A. *et al.*, 1997). Interestingly, mutating the corresponding cysteine residue in human rhodopsin (position 187) causes autosomal dominant RP (Richards, J. E. *et al.*, 1995).

These two different causes of inherited color-vision defects might be expected to have different retinal phenotypes. It is thought that all photoreceptors destined to become L or M cones will express either the first or second gene in the X-chromosome array (Hayashi, T. *et al.*, 1999). In the case of gene rearrangements, all photoreceptors are expected to express a gene that encodes a functional pigment; however, in the case of the inactivating mutation, a fraction of the photoreceptors will express a pigment that is not functional and, in fact, may be deleterious to the viability of the cell. Recently, it was discovered that there are different retinal phenotypes among red-green color-blind individuals. Carroll, J. *et al.* (2005) found that in individuals having either a single-gene array, or an array in which the first two genes both encode a pigment of the same spectral class, the cone mosaic is normal in appearance. In contrast, in an individual in which one of the genes in the array encodes a pigment with an inactivating mutation, dramatic loss of healthy cones was observed, consistent with the hypothesis that cells expressing the mutant pigment degenerated (Carroll, J. *et al.*, 2004). To date, there have been eight missense mutations reported in the L/M opsins (see Figure 5): N94K, R330Q, and G338E (Ueyama, H. *et al.*, 2002), W90X (Wissinger, B. *et al.*, 2006), P187S (Neitz, M. *et al.*, 2004), R247X and P307L (Nathans, J. *et al.*, 1993), and C203R (Winderickx, J. *et al.*, 1992).

Color blindness can also arise due to promoter mutations within the L/M array, though this does not appear to be common. A mutation (A-71C) in the proximal promoter of the second gene in the array has been associated with both deutan and protan color-vision defects (Ueyama, H. *et al.*, 2003; Neitz, M. *et al.*, 2004). Although the mechanism through which this mutation acts is not entirely clear, it is believed that it either reduces or abolishes gene expression (Ueyama, H. *et al.*, 2003). Disruptions in the LCR can prohibit the expression of any gene in the array (Nathans, J. *et al.*, 1989), as occurs in some cases of BCM (see below).

Finally, an even rarer cause of color blindness results from a swap in gene order. In normal individuals, the array features an L gene followed by one or more M genes (Nathans, J. *et al.*, 1986b; Neitz, M. and Neitz, J., 1995). There are however three reported cases in which an M gene occurs in the first position, with an L gene downstream (Neitz, M. *et al.*, 2004; Ueyama, H. *et al.*, 2006). In all cases, this gene arrangement is associated with a protan defect. Neitz, M. *et al.* (2004) described a male with five genes in the L/M array, where the L gene was in the last position. Previous work has suggested that only the first two genes in the L/M array are significantly expressed (Hayashi, T. *et al.*, 1999), so the protan phenotype of this individual is not surprising. Ueyama, H. *et al.* (2006) described two unrelated males each with four genes in their L/M array. Both had an L gene in the second position of the array, but the L gene also had the A-71C promoter mutation, a change believed to preclude the expression of the associated gene. This also is consistent with the observed protan phenotype. In the absence of any other disruptions in the L/M array, one would predict that an array with an M gene in the first position and an L gene in the second position would confer normal color vision, though such cases have not yet been observed.

1.09.6.2.2 Blue cone monochromacy

BCM is a condition where L- and M-cone function is absent (Pokorny, J. *et al.*, 1979). As with the red-green defects, there are two main genetic causes of BCM, sometimes referred to as one-step or two-step mutations (Nathans, J. *et al.*, 1989; 1993), though both lead to the absence of functional L- and M-photopigment molecules. One-step mutations involve a deletion of essential cis-regulatory DNA elements needed for normal expression of the pigment genes. Two-step mutations involve a deletion of all but one of the X-chromosome visual pigment genes. This would normally confer a red-green dichromacy, but the one remaining gene contains a missense mutation (two-step mutation). It is also possible, though less common, for multiple genes in the array to contain the missense mutation (Nathans, J. *et al.*, 1993; Crognale, M. A. *et al.*, 2001). In both the one-step and two-step mechanisms, affected individuals have very poor visual acuity, myopia, nystagmus, and minimally detectable ERG responses. Due to the X-linked nature of the condition, female carriers are spared from a full manifestation of the associated defects, but they can show abnormal cone ERG amplitudes (Berson, E. L. *et al.*, 1986). One-step and two-step conditions may have important phenotypic differences in terms of the architecture of the cone mosaic in carriers. For the one-step mutations, the absence of an essential

enhancer means that the cone photoreceptors cannot transcribe an opsin gene from the affected X-chromosome. In contrast, for the two-step condition, there is a completely functional gene, but the encoded opsin has a deleterious amino acid substitution, and the photoreceptor is expected to produce the mutant opsin. Depending on the nature of the mutation, it may either reduce or abolish proper folding of the encoded protein, or the gene may be transcribed but the message may be immediately targeted for degradation, and these may in turn ultimately affect the viability of the cone or its neighboring cells. While both conditions will compromise the viability of the cone, they are likely to do so over different time scales.

1.09.6.2.3 Tritan color-vision defects

Tritan color-vision deficiency is an inherited autosomal dominant abnormality of S-cone function (Wright, W. D., 1952). The disorder exhibits incomplete penetrance, meaning that individuals with the same underlying mutation manifest different degrees of color-vision impairment, even within a sibship (Kalmus, H., 1955; Cole, B. L. *et al.*, 1966; Pokorny, J. *et al.*, 1981; Miyake, Y. *et al.*, 1985; Went, L. N. and Pronk, N., 1985). Mutations in the S-cone opsin gene, which encodes the protein component of the S-cone photopigment, have been identified, and they give rise to five different single amino acid substitutions that have only been found in affected individuals but not in unaffected control subjects (Figure 8): G79R and S214P (Weitz, C. J. *et al.*, 1992a), P264S (Weitz, C. J. *et al.*, 1992b), L56P (Gunther, K. L. *et al.*, 2006), and R283Q (Baraas, R. C. *et al.*, in press). Each substitution occurs at an amino acid position that lies in one of the transmembrane α-helices and is predicted to interfere with folding, processing, or stability of the encoded opsin. For example, one of the identified mutations (Weitz, C. J. *et al.*, 1992b) corresponds to an amino acid position at which a substitution in the rod pigment, rhodopsin, causes autosomal dominant retinal degeneration (Sheffield, V. C. *et al.*, 1991; Hwa, J. *et al.*, 1997).

A fundamental difference between S cones and L/M cones is the potential for dominant negative interactions between normal and mutant opsins. This is because each S cone expresses both autosomal copies of the S-opsin gene, whereas L and M cones each only

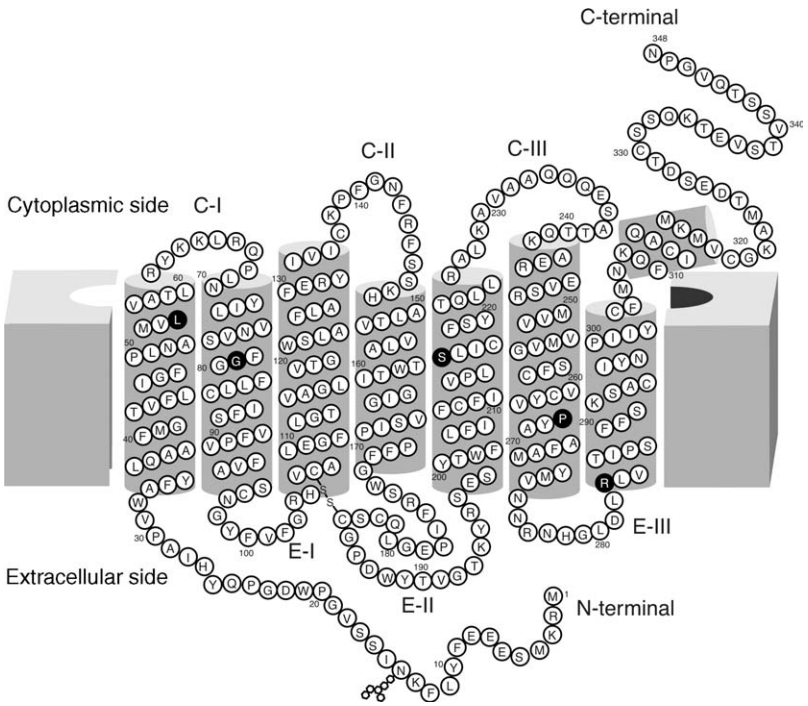

Figure 8 Two-dimensional model of human S opsin. Each circle represents a single amino acid, with tritan-causing mutations identified as filled circles. Adapted from Stenkamp, R. E., Filipek, S., Driessen, C. A. G. G., Teller, D. C., and Palczewski, K. 2002. Crystal structure of rhodopsin: a template for cone visual pigments and other G protein-coupled receptors. Biochim. Biophys. Acta Biomembranes 1565, 168–182, with permission.

expresses one opsin gene from the L/M array on the X-chromosome. Rod photoreceptors also express a rhodopsin gene from two autosomes, and for rhodopsin mutations underlying autosomal dominant RP, dominant negative interactions lead to the death of the photoreceptors and ultimately to the degeneration of the retina (see above). Curiously, tritan defects have not been reported to cause progressive retinal degeneration and are only slightly more rare than adRP; however, it has been suggested that the relative paucity of S cones compared to rods may be responsible for the absence of more general retinal degeneration (Weitz, C. J. *et al*., 1992a). Nevertheless, the structural homology between the S-cone opsin and rhodopsin, taken together with the similar molecular mechanisms underlying the defects, suggests that S cones themselves do degenerate in autosomal dominant tritan defects (Baraas, R. C., *et al*. 2007).

Acknowledgment

We thank K. Palczewski for assistance with photopigment diagrams, E. Kelly and P. Summerfelt for assistance in preparing the figures, M. Cheetham, T. Dryja, L. Sullivan, and D. Tait for assistance in compiling rhodopsin mutation data, and J. Neitz, M. Neitz, and T. Sakmar for helpful comments.

Glossary

background-light adaptation The process by which rod and cone photoreceptors change their response properties due to the presence of a steady background light. The photoreceptor becomes less sensitive to light, and the response also becomes faster.

bleaching The loss of color of the visual pigment due to the loss of its ability to absorb in the visible part of the spectrum. In the dark state, a holo pigment (opsin plus chromophore) absorbs light in a specific part of the visible spectrum. After absorbing a photon, the chromophore isomerizes and eventually separates (by hydrolysis) from the opsin. As a result, neither the chromophore nor the opsin absorbs in the visible spectrum anymore, until regeneration of the pigment.

bleaching adaptation The process by which rod and cone photoreceptors change their response properties when a significant fraction of their visual pigment content has lost the chromophore (see Chromophore) after light absorption (see Bleaching). Bleaching adaptation results from both loss of pigment due to bleaching and a mild activity of the opsin apoprotein.

chromophore A light-absorbing moiety. For visual pigments, the chromophore is 11-*cis*-retinaldehyde, which is a derivative of vitamin A (all-*trans*-retinol). It is covalently linked (via a Schiff base) to a lysine residue in the opsin apo-protein.

dark adaptation The process by which a photoreceptor recovers its sensitivity in darkness after exposure to a bleaching light.

electroretinogram An en-mass electrical recording from the retina of an animal or human eye. Different components reflecting the electrical activities of different types of retinal neurons can be identified in the electroretinogram. This is a very useful tool for clinical diagnosis of abnormal function in the retina.

parietal eye A primitive eye present in some lower vertebrates, especially lizard. It is an unpaired, midline organ on the forehead, not for acute vision (as the two lateral eyes) but most likely for detecting the passage of time during the day.

phototransduction The process by which light triggers an electrical response in retinal rod and cone photoreceptors.
single-photon response The response of a photoreceptor to a single absorbed photon. It is the fundamental building block of all light responses, containing precious information about the process of phototransduction.

1.10.1 Introduction

The physiology of rods and cones is conserved across animal species. Rods are extremely sensitive to light. The ingenious work of Hecht S. *et al.* (1942) has shown that these cells, when fully dark-adapted, are capable of signaling the absorption of a single photon. They mediate vision in dim light (scotopic vision). Cones, on the other hand, are less sensitive to light than rods, typically by two orders of magnitude under dark-adapted conditions. Moreover, whereas rods have only a limited ability to adapt to steady light, cones have a much higher adaptive ability. Accordingly, cones function in bright light (photopic vision). They also have faster response kinetics than rods, which makes them more suitable for the detection of motion. In addition, because there is typically more than one type of cone in the retina, each expressing a different photopigment, cones endow the animal with the ability of color vision. Most retinas are rod-dominant, but a minority of animal species, such as ground squirrel and chicken, have cone-dominant retinas. In the human retina, 95% or more of the photoreceptors are rods, but its center, the fovea, where acute vision occurs, has exclusively cones.

1.10.2 Morphology of Rods and Cones

Rods and cones are quite similar in structure (Cohen, A. I., 1987; Dowling, J. E., 1987; Rodieck, R. W., 1998). Each has an elongated outer segment, an inner segment, a cell body, and a synaptic terminal (Figure 1). Light traverses the entire thickness of the retina before being absorbed in the outer segment, where it triggers an electrical signal via a cascade of intracellular signaling events (visual transduction or phototransduction). The outer segment is actually a modified cilium that, during the development of the photoreceptor, has become highly expanded and convoluted so that the plasma membrane is folded upon itself hundreds of times (Steinberg, R. H. *et al.*, 1980). These so-called membranous disks, tightly stacked one on top of another and oriented perpendicular to the longitudinal axis of the outer segment, are densely embedded with the visual pigment, a transmembrane protein. Packed at a density as high as $30\,000\,\mu m^{-2}$ of membrane, there are altogether $\sim 10^8$ rod pigment (rhodopsin) molecules in a single mammalian rod. The number in an amphibian rod, such as that of toad, is tenfold even higher because of its larger outer segment. One convenient way to calculate the number of rhodopsin molecules in a rod outer segment is to simply multiply the volume of the outer segment by 3.5 mM, the effective pigment concentration (Harosi, F. I., 1975). The packing density of cone

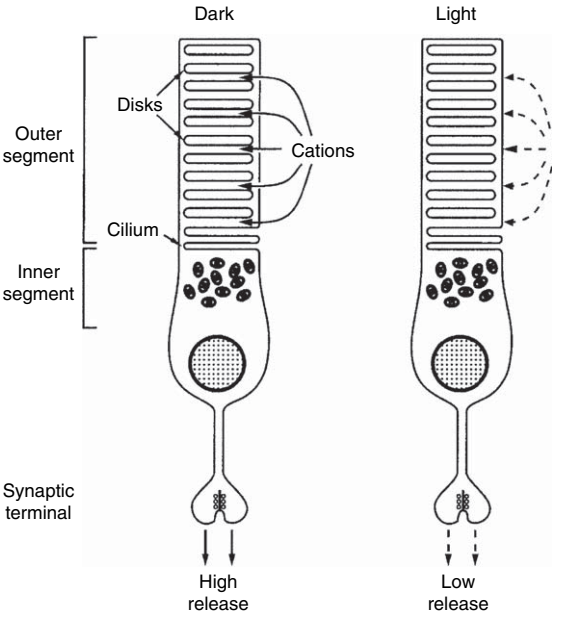

Figure 1 Diagram to show the overall morphology of a retinal rod photoreceptor and the behavior of its dark current in darkness and in the light (see text for details). Reproduced with permission from Yau, K.-W. 1994. Phototransduction mechanism in retinal rods and cones. The Friedenwald Lecture. Invest. Ophthalmol. Vis. Sci. 35, 10–32.

pigment in the membrane is similar. The disks are clearly designed for increasing the probability of absorption as a photon travels longitudinally through the outer segment. For example, the chance that a 500-nm photon (wavelength of maximum absorption for rhodopsin) will be absorbed upon longitudinally traversing a 15-μm-long mouse rod outer segment is almost 50%!

In rods, almost all of the disks (except for a small number at the base of the outer segment) are completely internalized, that is, no longer continuous with the plasma membrane. In cones, the disks do remain continuous with the plasma membrane (Cohen, A. I., 1987). These disks undergo continual renewal, with new disks being formed daily at the base of the outer segment (i.e., next to the inner segment) and a corresponding number shed at the tip, so that the total number remains more or less constant (La Vail, M. M., 1983). This renewal process may be important for removing any cumulative, harmful effects of photo-oxidation in the photoreceptors. It takes about 10 days for a mouse or rat rod to renew its entire outer segment.

Overlying the outer segments of rods and cones are the pigment epithelial cells. These cells serve multiple functions (Steinberg, R. H., 1985). One function is, by virtue of the melanin granules they contain, to absorb any light not absorbed by the rods and cones at a single pass, so as to prevent degradation of the visual image due to backscattering. A second function is to transport metabolites, ions, water, and other substances between the photoreceptors and the blood capillaries in the choriocapillaris on the opposite side of the pigment epithelium. Third, these cells contain the machinery critical for the regeneration of the visual pigment after the latter is bleached by light. Fourth, they phagocytize the shed disks at the tip of the outer segment.

1.10.3 Light Response of Rods and Cones

The membrane potential of rods and cones in darkness is at −30 to −35 mV. This potential is sufficiently depolarized to activate synaptic L-type Ca channels and trigger neurotransmitter (glutamate) release. Light produces a membrane hyperpolarization at the outer segment, which propagates electrotonically to the synaptic terminal and reduces the glutamate release. The response is graded with light so that the brighter the light, the larger is the membrane hyperpolarization and the greater the reduction in glutamate release. There are two types of bipolar cells, the second-order retinal throughput neurons receiving synaptic inputs from rods and cones. One type responds to light with a hyperpolarization (OFF-bipolar cell) and the other responds with a depolarization (ON-bipolar cell). OFF-bipolar cells use postsynaptic ionotropic glutamate receptors on their dendrites (so that the synapse is sign-preserving), whereas ON-bipolar cells use a metabotropic glutamate receptor (type 6) and a downstream second-messenger pathway (the details of which are still unclear; see Chapter Contributions of Bipolar Cells to Ganglion Cell Receptive Fields) that lead to a sign-inverting synapse.

The rod and cone responses to light are relatively slow, reflecting a second-messenger-mediated transduction mechanism (see Section 1.10.10). For example, amphibian rods at room temperature respond to a dim flash with a hyperpolarization that reaches a transient peak in approximately 1 s and takes another 1–3 s to subside (Figure 2(b)). The light response of mammalian rods (37 °C) is severalfold faster (Baylor, D. A., 1987). For a given animal species, cones are also up to severalfold faster than rods in response kinetics. The speed of the response dictates how rapidly a photoreceptor is capable of detecting image changes on the retina (temporal resolution), and therefore motion. Because cones have faster responses than rods, they are better motion detectors. On the other hand, the slower response of rods allows these cells to sum signals dispersed over time (temporal integration), thus enhancing the sensitivity in dim light especially for static images.

Historically, the photoreceptors of cold-blooded animals (fish, amphibians, and reptiles) have been favorite preparations for electrophysiological studies because of their large size and hardiness. The pioneering studies by Tomita and colleagues with sharp intracellular microelectrodes on fish first showed that retinal photoreceptors hyperpolarize to light and that this is due to a light-induced decrease in membrane conductance, presumably in the outer segment (Tomita, T., 1970). Subsequently, Hagins W. A. *et al.* (1970) used a linear array of three microelectrodes to map the current flow around the rod photoreceptors in the rat retina, demonstrating that a membrane current (the dark current) enters the rod outer segment and exits from the rest of the cell in darkness and that this current is suppressed by light (Figure 1). These findings corroborated those of Tomita and coworkers. With the advent of the suction-pipette recording method in the 1970s (Yau, K.-W. *et al.*,

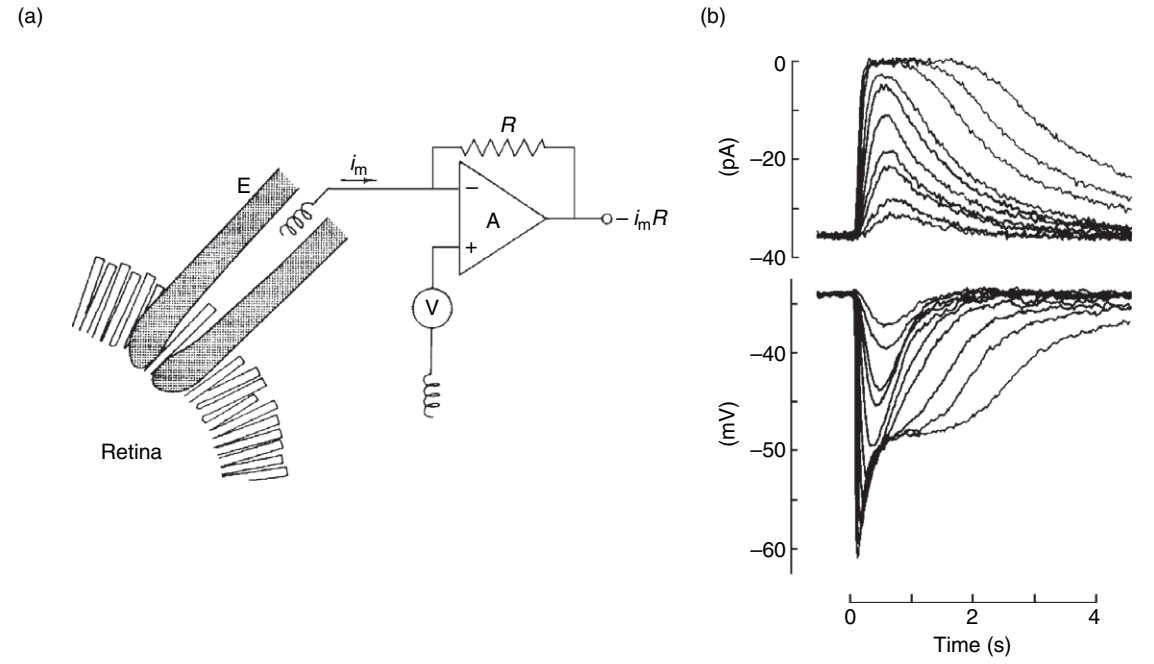

Figure 2 (a) The schematics of the suction-pipette method for recording from a photoreceptor. (a) Reproduced from Yau, K.-W., Lamb, T. D., and Baylor, D. A. 1977. Light-induced fluctuations in membrane current of single toad rod outer segments. Nature 269, 78–80. (b) Simultaneous current and voltage recordings from a salamander rod. (b) Reproduced with permission from Baylor, D. A., Matthews, G., and Nunn, B. J. 1984. Location and function of voltage-sensitive conductances in retinal rods of the salamander, Ambystoma tigrinum. J. Physiol. 354, 203–223.

1977), it has now become almost routine to record from the rods and cones of not just cold-blooded vertebrates, but also a variety of mammals, including humans. This recording method, inspired by the patch-clamp technique (Neher, E. and Sakmann, B., 1976), consists typically of drawing the outer segment of an isolated rod or cone, or an outer segment projecting from a fragment of retina, into a tight-fitting glass pipette filled with physiological extracellular solution and connected to a current-to-voltage transducer for recording membrane current (Figure 2(a)) (Baylor, D. A. *et al.*, 1979a; Schnapf, J. L. and McBurney, R. N., 1980). This method is simple, noninvasive, and stable, allowing continuous recordings without degradation for up to several hours.

Figure 2(b) shows simultaneous recordings from a salamander rod with a suction pipette and a sharp intracellular electrode (Baylor, D. A. *et al.*, 1984). In darkness, the membrane potential is −35 mV and there is a steady dark current of 20 pA entering the outer segment (it is conventional in the field of visual transduction to plot the membrane current flowing at the outer segment, with a negative sign to indicate inward current). In response to a light flash, the dark current transiently decreases and the membrane potential hyperpolarizes. With increasing flash intensity, the light response increases in a graded fashion until it saturates, corresponding to a complete suppression of the dark current (Hagins, W. A. *et al.*, 1970; Baylor, D. A. *et al.*, 1979a). Note that the current and voltage responses are similar in shape (as well as in kinetics, except that the voltage response reaches peak slightly earlier) with dim flashes but differ dramatically with bright flashes, in that the voltage response but not the current response shows a fast redepolarization from the peak hyperpolarization before settling to a plateau level. This transient nose in the voltage response, especially prominent in rods, reflects a hyperpolarization-activated cation current (I_h) carried by both Na^+ and K^+, with a reversal potential very roughly near 0 mV (Fain, G. L. and Lisman, J. E., 1981; Accili, E. A. *et al.*, 2002). The I_h current presumably also underlies the slightly earlier peak of the voltage response compared to that of the current response to dim light. This I_h current is situated at the inner segment and cell body. Because the light-sensitive conductance is the only ion conductance on the plasma membrane of the outer segment (Baylor, D. A. and Lamb, T. D., 1982), and

because it has an essentially flat current–voltage relation in the physiological voltage range (at least for the rod channel; see Section 1.10.9), the nose is not detected by the suction pipette (Baylor, D. A. *et al.*, 1979a). Some of these subtle properties were not anticipated when the suction-pipette method was first developed, but they have made the method tremendously useful for monitoring phototransduction in the outer segment, without much contamination by signals from other parts of the cell.

Another useful configuration of the suction-pipette method is to draw the cell body and inner segment of an isolated rod or cone photoreceptor into the suction pipette for recording (Figure 3(b)) (Yau, K.-W. *et al.*, 1981). Because current flows in a closed loop (dark current entering the outer segment through the light-sensitive conductance and exiting the rest of the cell through other conductances), the same current but of the opposite polarity is recorded in this configuration. This recording configuration has the advantage that the solution surrounding the outer segment can be changed selectively and rapidly, which turned out to be crucial for elucidating the mechanism of phototransduction. Being noninvasive, however, suction-pipette recording from a rod or cone does not allow internal dialysis of the cell, an often-useful manipulation. Internal dialysis can be achieved by another variant of the method, which consists of sucking the outer segment into the pipette and truncating the base of the outer segment for rods (Yau, K.-W. and Nakatani, K., 1985b), or the inner segment for cones (Nakatani, K. and Yau, K.-W. 1986; Rieke, F. and Baylor, D. A., 2000), situated outside the pipette in order to expose the interior of the recorded outer segment to the bath solution (Figure 3(c)). In this way, with the appropriate metabolites in the bath solution, the outer segment remains capable of transducing light for minutes or longer by virtue of the retained transduction proteins, most of which are transmembrane or peripheral membrane proteins rather than soluble. Depending on the question to be addressed, one recording configuration is more useful than another.

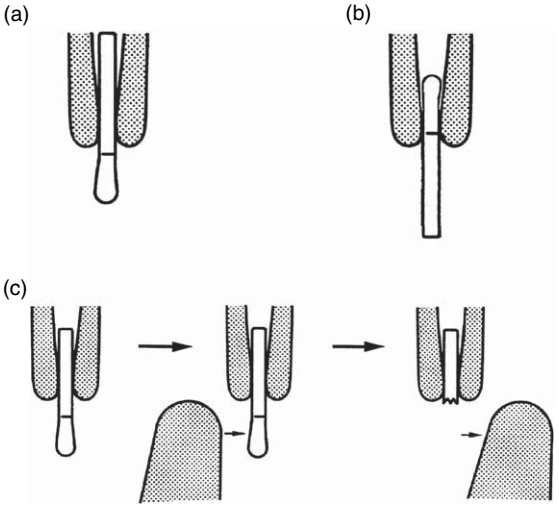

Figure 3 Three configurations of the suction-pipette recording method. (a) Outer segment inside the pipette. (b) Outer segment outside the pipette for perfusion purposes. (c) The truncated-outer-segment preparation.

Because of its usefulness, the suction-pipette method and its measured light responses will form the basis for all discussions to follow.

1.10.4 Intensity–Response Relation

In this chapter, we define a flash as a short-lasting light stimulus with a time duration that is negligible compared to the time course of the elicited response from the cell – with the flash preferably over before the response even becomes visible. In engineering terminology, a flash is an impulse, and the response to a flash is the impulse response. The advantage of the flash response is that, once it is known, the response to a more complex light stimulus (in intensity or duration) can be obtained by mathematically convolving the flash response with the light stimulus. The rigorous use of light flashes (typically 10–20 ms in duration) as defined above for studying retinal rods and cones was not adopted until Hodgkin A. L. and his disciples started using them routinely in the early 1970s (Baylor, D. A. and Hodgkin, A. L., 1973).

When the amplitude of the transient peak of the flash response is plotted against the corresponding flash intensity (the flash intensity–response relation at response peak), the relation can be described moderately well, especially for cold-blooded animals, by the Michaelis equation used in enzyme kinetics, namely, $R = R_{max}[I_F/(I_F + \sigma)]$, where R is the transient peak amplitude, R_{max} the saturated response amplitude (i.e., complete suppression of the dark current), I_F the flash intensity, and σ the half-saturating flash intensity (Figure 4(a)). The Michaelis equation is often called the rectangular hyperbola in vision research because, when plotted on coordinates of response versus log-intensity as commonly done, it assumes the shape of a rectangular hyperbola. The fact that the Michaelis equation provides a

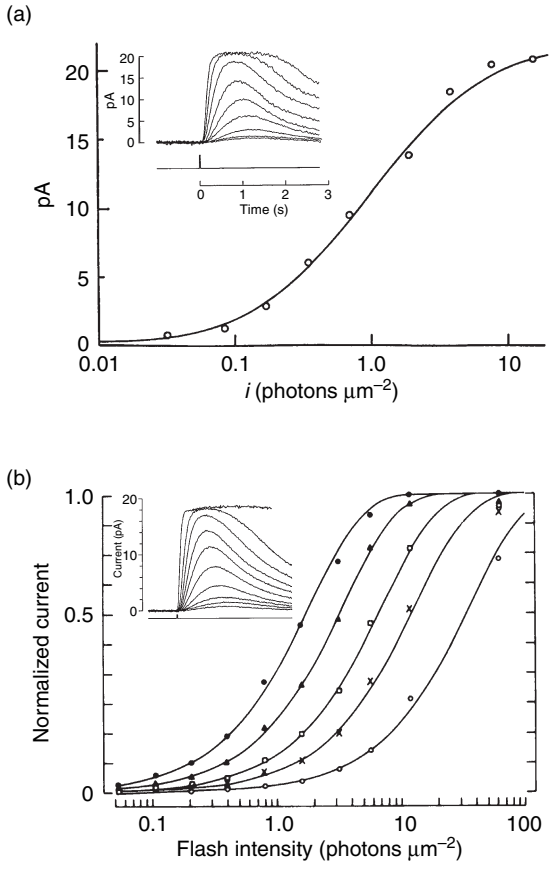

Figure 4 (a) Intensity–response relation at transient response peak of a toad rod recorded with the suction-pipette method. Outer segment inside the pipette. 500 nm, 20 ms flash (plane polarized transverse to the longitudinal axis of the outer segment) over the entire outer segment. Plot shows the transient peak response amplitude against incident flash intensity. The smooth curve is the Michaelis equation, with $\sigma = 1$ photon μm^{-2}. (b) Instantaneous flash intensity–response relation of a toad rod. Similar experimental conditions as in (a). The various symbols indicate the relation at different time instants on the rising phase of the flash response. The smooth curves are all drawn according to the saturating exponential function $1 - \exp(-I_F/\rho)$. This function is steeper than the Michaelis equation. (a) Reproduced with permission from Baylor, D. A., Lamb, T. D., and Yau, K.-W. 1979a. The membrane current of single rod outer segments. J. Physiol. 288, 589–611. (b) Reproduced with permission from Lamb, T. D., McNaughton, P. A., and Yau, K.-W. 1981. Spatial spread of activation and background desensitization in toad rod outer segments. J. Physiol. 319, 463–496.

moderately good fit to the flash intensity–response relation at response peak, together with the conceptual association of this equation with equilibrium binding, evoked early interest in interpreting the phototransduction mechanism according to a scheme of equilibrium binding between a second messenger and the light-suppressible conductance (Baylor, D. A. and Fuortes, M. G. F., 1970), especially in view of the prevailing Ca^{2+} hypothesis for phototransduction at the time (see Section 1.10.10). However, it later became clear that this approximate agreement between the Michaelis equation and the peak response–intensity relation is just accidental, with no deep implications about any simple mechanistic link between the two. Hodgkin and colleagues (Baylor, D. A. *et al.*, 1974) were again the first to point this out. For one thing, with increasing flash intensity, the transient peak of the response moves earlier in time; that is, the time between the flash and the transient peak of the response (or time-to-peak) gets shorter (Figure 2 or 4(a)). This speeding up of the response indicates that the decay phase of the response cuts into the rising phase progressively earlier with increasing flash intensity, an indication of active adaptation by the cell. Because the time-to-peak changes with increasing flash intensity, the intensity–response relation at transient peak is therefore not measured at a constant time, and any fit to the Michaelis equation (in which time is not a variable) has to be purely empirical. Hodgkin and colleagues (Baylor, D. A. *et al.*, 1974) first introduced the idea of an instantaneous intensity–response relation, meaning a relation measured at a fixed time instant after the flash (so that the time variable is removed), typically at an early time in the rising phase of the light response, before any active adaptation has set in. In this case, the flash intensity–response relation is better described by the saturating exponential function $R = R_{max}[1 - \exp(-I_F/\rho)]$, where the half-saturating flash intensity is given by $\rho(\log_e 2)$ (Figure 4(b)). This function is steeper than the Michaelis equation (Baylor, D. A. *et al.*, 1974; Lamb, T. D. *et al.*, 1981). It also bears a simple mechanistic interpretation, namely that each absorbed photon activates a spatially restricted domain on the outer segment, within which transduction essentially reaches saturation (i.e., all dark current within this domain is suppressed). While conceptually useful, this compartment model nonetheless should not be taken too literally. On the other hand, the idea of a fairly restricted spread of phototransduction elicited by the absorption of a photon is certainly valid and could be directly demonstrated (Lamb, T. D. *et al.*, 1981) with a light slit stimulating only a small longitudinal portion of the rod outer segment (see also Section 1.10.7).

If a long step (say, many seconds) instead of a flash of light is used for stimulation, the rod or cone response rises to a transient peak and then relaxes to a lower plateau level (Figure 5(a)). This response relaxation again reflects the progressive development of active adaptation by the cell to steady light (Baylor, D. A. *et al.*, 1979a; 1979b; 1980; Nakatani, K. and Yau, K.-W., 1988a). If the intensity–response relation (in this case often called the step intensity–response relation) is plotted at different fixed time points after the onset of light, the relation at early times after light onset is describable by the above saturating exponential function just as the instantaneous flash intensity–response relation, but it becomes progressively shallower with time (Nakatani, K. and Yau, K.-W. 1988a). In the plateau phase of the step response, the step intensity–response relation is shallower than even the Michaelis equation, being describable by a logarithmic rise (Figure 5(b); Nakatani, K. *et al.*, 1991) (see also Section 1.10.12).

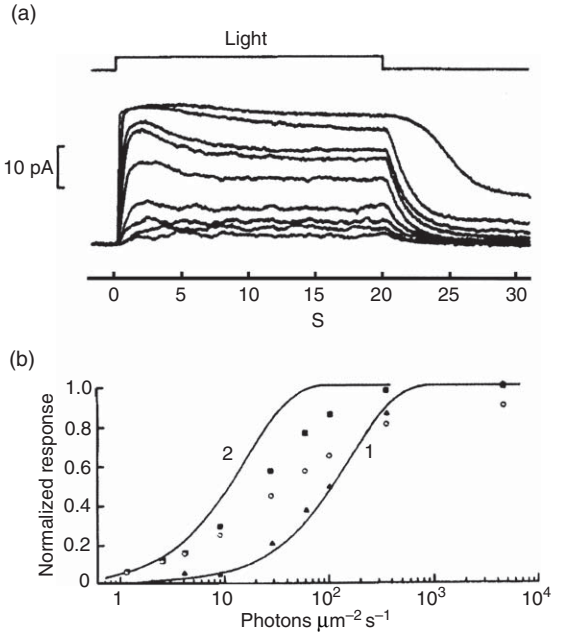

Figure 5 (a) Response family elicited by a light step of different intensities from a salamander rod. Similar experimental conditions as in Figure 4. Note the relaxation of the response at early times during the light step. (b) Step intensity–response families at different times of the response. Filled triangles: 0.4 s after light onset; filled squares: transient response peak; open circles: at plateau just before light off. Curves 1 and 2 are both drawn according to the saturating exponential function. Reproduced with permission from Nakatani, K. and Yau, K.-W. 1988a. Calcium and light adaptation in retinal rods and cones. Nature 334, 69–71.

The sensitivity of a rod or cone can be represented in two ways. One way is to simply use the value of σ (i.e., half-saturating flash intensity) as an indicator of sensitivity, with σ being inversely proportional to sensitivity. Sometimes, however, it is more informative to describe flash sensitivity as the transient peak amplitude of the response elicited by one absorbed photon in a weak flash (single-photon response). This latter parameter can be obtained from (and is only meaningful in) the linear range of the flash intensity–response relation by dividing the linear response amplitude by the calculated number of absorbed photons. The linear range refers to the foot of the intensity–response relation at low flash intensities such that doubling the intensity will exactly double the response, with negligible change in response kinetics (including negligible shift in the time-to-peak) (Baylor, D. A. and Hodgkin, A. L., 1973; Baylor, D. A. *et al.*, 1974). A linear foot of the intensity–response relation is implicit in the fitting by either the Michaelis equation or a saturating exponential function described above, because both are linear at low flash intensities (see Section 1.10.7 for more details). With suction-pipette recording, for which light is typically incident roughly at right angles to the longitudinal axis of the outer segment, the number of absorbed photons effected by a flash at low intensities is (assuming diffuse light that covers the entire outer segment) given by $I_F A_e$, where I_F is the number or equivalent number of incident photons per square micrometer contained in the flash at λ_{max} (the wavelength of maximal absorption for a given pigment), and A_e is the effective collecting area given by $A_e = 2.303(\pi d^2 L/4) Q_{isom} f \alpha$, where d and L are, respectively, the outer-segment diameter and length, Q_{isom} is the quantum efficiency of isomerization (equal to 0.67 for pigments containing 11-*cis*-retinal as chromophore), α is the axial optical density (in the neighborhood of 0.016 μm^{-1}), f is a factor equal to unity for plane-polarized light parallel to the membrane disks and equal to 0.5 with unpolarized light, and 2.303 is simply from $\log_e 10$ (Baylor, D. A. *et al.*, 1979b). For light that is incident along the outer-segment axis, as in situ in the eye, the number of absorbed photons is no longer directly proportional to the length of the light path in the outer segment because of self-screening by the pigment along the long light path. In this case, the percentage of absorbed photons is given by $1 - 10^{-\alpha L}$, where α is again the axial optical density as above and L the length of the outer segment. In this case, whether the light is unpolarized or plane-polarized makes no

difference. Finally, the single-photon response amplitude can also be estimated without the knowledge of the incident light intensity and the effective collecting area of the outer segment, by using variance analysis of the response amplitude, provided that the response lies in the linear range (Baylor, D. A. *et al.*, 1979b) (see Section 1.10.7). In principle, the same parameter can be resolved from the experimental response amplitude histogram derived from dim flashes, but, in practice, this is not an easy method unless the histogram is optimized in the experiment (Figure 9(b)).

If flash sensitivity is designated by S_F (in unit of picoamperes per photon), one can write the step sensitivity, S_S (defined as the steady response elicited by a continuous light causing one absorbed photon per second, and in unit of picoamperes per photon per second), as simply $S_S = S_F t_i$. Here t_i is the integration time of the (linear) response elicited by a dim flash, defined as $t_i = \int f(t)dt/f_p$, where $f(t)$ is the response profile of the single-photon response and f_p the amplitude of $f(t)$ at transient peak (Baylor, D. A. and Hodgkin, A. L., 1973). The integration time gives a measure of the effective lifetime of the dim-flash response. The mean steady response produced by a weak continuous light at intensity I_S (in units of absorbed photons per second at λ_{max}) is then $S_S I_S$. This relation holds, of course, only in the linear range of the intensity–response relation.

The above concepts and parameters, first introduced by Hodgkin and colleagues, have greatly facilitated the study of the physiology of rods and cones by providing a rigorous foundation.

1.10.5 Kinetics of the Dim-Flash Response

The kinetics of the dim-flash response provides empirical information about the underlying transduction mechanism. For example, the profile of the rod dim-flash response can generally be fitted by the convolution of a series of four linear delay stages (Figure 6(a); Baylor, D. A. *et al.*, 1979a). In other words, the foot of the response increases sigmoidally as the third power of time, and the final decline follows a single exponential. Depending on the cell, the time constants of the delay stages may be similar or different from each other, although such details are not necessarily very informative or precise, other than reflecting some variability from cell to cell in one or more of the underlying delay stages. One of several formal schemes compatible with the kinetics

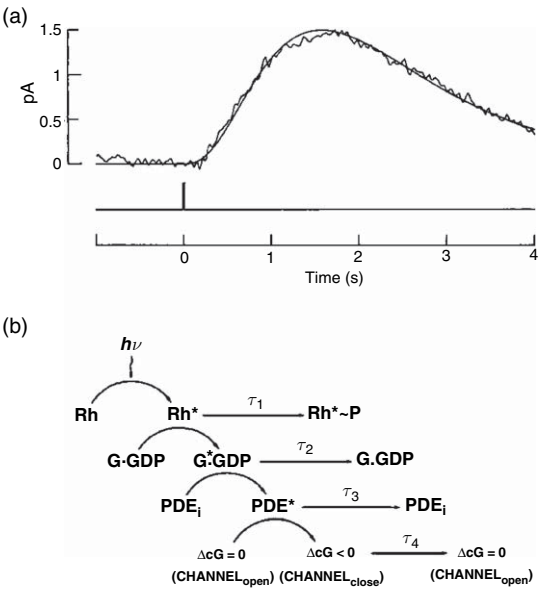

Figure 6 (a) Average dim-flash response from a toad rod. Smooth curve shows fit with a function corresponding to the convolution of four single-exponential decays. (b) Diagram showing a formal kinetic scheme that can describe the dim-flash response. The transduction components are inserted based on the underlying mechanism known much later. The states marked by '$*$' are active. The various τs indicate decay time constants. (a) Reproduced with permission from Baylor, D. A., Lamb, T. D., and Yau, K.-W. 1979a. The membrane current of single rod outer segments. J. Physiol. 288, 589–611. (b) Reproduced with permission from Yau, K.-W. 1994. Phototransduction mechanism in retinal rods and cones. The Friedenwald Lecture. Invest. Ophthalmol. Vis. Sci. 35, 10–32.

is shown in Figure 6(b) (Matthews, G. and Baylor, D. A., 1981; Yau, K.-W., 1994), so chosen because it happens to match more or less the underlying biochemistry subsequently worked out. For a linear system, the delay stages are commutative, that is, giving the same overall response profile regardless of their order in the cascade. Thus, the slowest step in the cascade, as reflected by the final exponential decay of the response, does not have to be the last step in the kinetic scheme at all. The scheme in Figure 6(b) is conceptual only, and not meant to be precise. With the underlying biochemistry now understood in great detail, a more precise formulation is realized (Pugh, E. N. and Lamb, T. D., 2000; Hamer, R. D. *et al.*, 2005).

Hodgkin and colleagues were the first to point out that when the light response is driven to saturation and beyond by an ever-increasing strong flash, the time of peeling off of the decline phase of the response from saturation is progressively delayed, with a duration

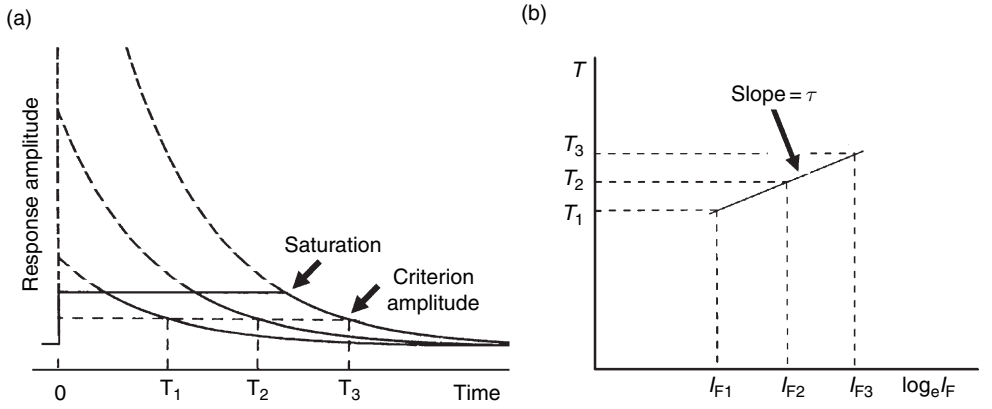

Figure 7 Diagram showing the concept of the Pepperberg time constant. (a) For simplicity, the response is taken to be a single-exponential-decline function (with time constant τ) that increases in amplitude in proportion to the flash intensity (I_F) and is subject to clipping by a saturation ceiling. Times T_1, T_2, etc. represent the progressive delay for the response to decay back to a criterion amplitude with increasing flash intensity. (b) Plot of T against $\log_e I_F$, with the slope giving τ.

that is proportional to the logarithm of the flash intensity (Baylor, D. A. *et al.*, 1974). The proportionality constant in fact corresponds to the time constant of the final exponential decay of the dim-flash response mentioned above. This idea was later popularized by Pepperberg D. R. *et al.* (1992), and the time constant has come to be referred to as the Pepperberg time constant or dominant time constant. This concept can be appreciated as follows. For simplicity, let us just consider a light response that obeys an underlying driving function, $AI_F \exp(-t/\tau)$, that is, one that has an amplitude proportional to the flash intensity, I_F, with a proportionality factor A and has a single-exponential decline with time constant τ, but the response is subject to a ceiling (saturation) that clips the would-be response beyond saturation (Figure 7). If we choose a constant criterion response amplitude at or below saturation, we have, if τ stays constant:

$$AI_F \exp\left(\frac{-t}{\tau}\right) = \text{constant}$$

or

$$t = \tau \log_e I_F + \text{constant}$$

Thus, in a plot of t against $\log_e I_F$, τ is simply equal to the slope.

1.10.6 The a-Wave of the Electroretinogram

The rod and cone photoresponses are detectable in the electroretinogram (ERG), a mass-recording from the retina with an electrode placed near the cornea of the intact eye (Berson, E. L., 1987). The ERG has several components, but the negative a-wave, which is one of the earliest components, reflects the activity of rods and cones (Figure 8). However, the a-wave does not provide the full-time profile of the photoreceptor response to light because the closely following b-wave of the ERG (which largely reflects the activity of ON-bipolar cells) cuts into and obscures the a-wave. The ERG nonetheless provides a very useful clinical tool for monitoring rod and cone function in human patients (Berson, E. L, 1993).

1.10.7 Single-Photon Response

It was mentioned earlier that rods are so sensitive to light that they are capable of signaling the absorption of a single photon (Hecht, S. *et al.*, 1942). This rod single-photon response is quite large, corresponding to a transient reduction in the dark current by ~0.5–1 pA in both amphibians and mammals (Penn, R. D. and Hagins, W. A., 1972; Baylor, D. A. *et al.*, 1979b; Baylor, D. A. *et al.*, 1984). In the isolated rod, this current amplitude should produce a membrane hyperpolarization in the neighborhood of 1 mV (Fain, G. L., 1975; Detwiler, P. B. *et al.*, 1980; Schneeweis, D. M. and Schnapf, J. L., 1995). When this transient change in current triggered by a photon is 1 pA or higher, it is readily detectable with suction-pipette recording (Baylor, D. A. *et al.*, 1979b). For stimulation with very weak flashes so that no photons are absorbed in a good percentage of the trials, the single-photon response is visible as the elementary unit underlying the quantal fluctuations in the response amplitude (Figure 9(a)). For stimulation with a very weak step of light, the single-photon responses reveal themselves as the sporadic, randomly occurring quantum bumps in the dark current when the light is on (Figure 9(c)). With a dark

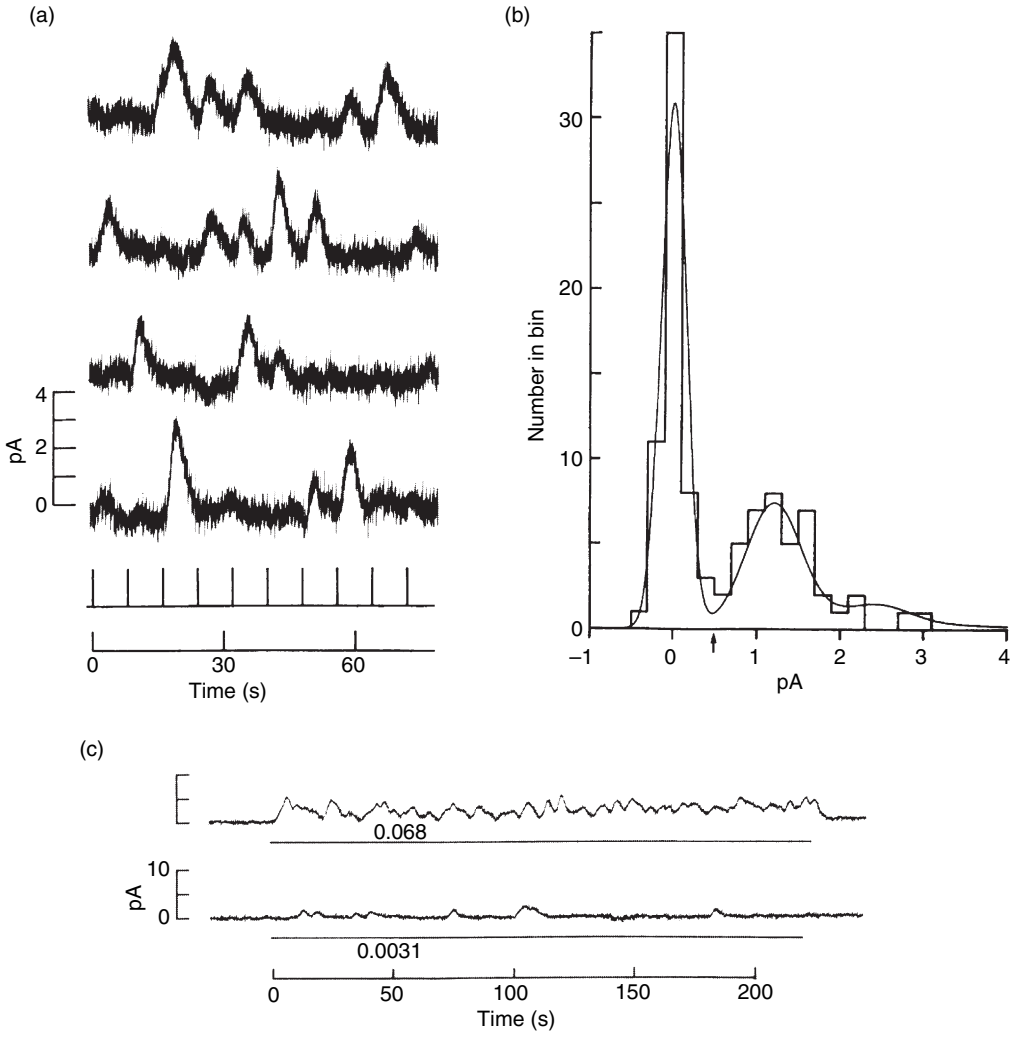

Figure 9 Single-photon responses recorded from toad rods. (a) Quantal fluctuations of a rod's responses to successive identical dim flashes. (b) Response amplitude histogram. The peak centered at 0 represents background noise; the peak centered near 1 pA represents the average response to a single absorbed photon. (c) Responses of a rod to a continuous dim light (timing given by horizontal line) at two different intensities (numbers above lines, in incident photons (500 nm) $\mu m^{-2} s^{-1}$). Reproduced with permission from Baylor, D. A., Lamb, T. D., and Yau, K.-W. 1979b. Responses of retinal rods to single photons. J. Physiol. 288, 613–634.

current in amphibian rods of typically ~20–40 pA, the single-photon response corresponds to about 3% of the maximum light response. In other words, as few as ~30 absorbed photons will elicit a half-maximum response from a rod. This large signal reflects the high amplification of the phototransduction mechanism in rods (see Section 1.10.10).

It was mentioned in Section 1.10.4 that the effect of an absorbed photon does not spread far along the outer segment (Lamb, T. D. *et al.*, 1981). Considering that the single-photon response in rods constitutes ~3% of the saturated response, the physical domain it occupies should be at least 2 μm along a toad or frog outer segment (~60 μm long). This minimum value corresponds to the situation where all dark current within the domain is suppressed (this is essentially the compartment model underlying the described saturating exponential function that fits the instantaneous flash intensity–response relation). The restricted spread is due largely to the tightly packed membranous disks, which constitute a barrier to longitudinal diffusion in the outer segment, thus confining the phototransduction event (Lamb, T. D. *et al.*, 1981). Radial diffusion, on the other hand, is relatively fast, so that phototransduction can be considered to be radially homogeneous (Lamb, T. D. *et al.*, 1981).

It was also mentioned in Section 1.10.4 that, at very low flash intensities, the response rises in direct proportion to (i.e., linearly with) flash intensity. In other words, the single-photon responses sum linearly when there are few of them occurring. It might not be immediately obvious why this linearity should be the case, considering that the phototransduction mechanism is intrinsically nonlinear (see Section 1.10.10). This linear foot is in fact the consequence of the spatially restricted domains occupied by individual single-photon responses. Thus, at very low intensities, when few photons are absorbed in an outer segment, the respective transduction domains are spatially isolated from each other (i.e., nonoverlapping). Consequently, the overall response is simply a linear sum of the responses contributed by the individual domains, hence a linear foot of the intensity–response relation. This linearity is independent of the intrinsic nonlinearities in the phototransduction process within each domain because under this condition it is simply the number of domains that matters. The linearity also makes the Poisson distribution applicable for analyzing the fluctuations in the responses elicited by identical dim flashes (much as what Bernard Katz and colleagues have first used for analyzing quantal release in synaptic transmission; del Castillo, J. and Katz, B., 1954). Essentially, the fluctuations are interpreted to result from the stochastic variations in the number of absorbed photons from flash trial to flash trial. As such, the single-photon response, which is the fundamental (or quantal) unit underlying the stochastic variations, can be evaluated from the ensemble variance/mean ratio of the response amplitude (variance analysis) (Baylor, D. A. *et al.*, 1979b). The advantage of this approach is that it does not require a priori knowledge of the mean number of absorbed photons resulting from a flash. When the probability of even one photon being absorbed in a flash is low, one obtains a response amplitude histogram as shown in Figure 9(b), which reveals the single-photon response as the first nonzero peak (provided that this amplitude is large enough to be well resolved from background noise). The overall amplitude histogram profile also obeys the Poisson distribution.

Within a given cell, the single-photon response is remarkably constant in both amplitude and kinetics from flash trial to flash trial – properties that make rods a very faithful photon counter at low intensities. How this constancy comes about was a question of great interest for years. If a photoactivated rhodopsin molecule is fully inactivated in a single molecular step, its active lifetime should be stochastic, that is, varying from rhodopsin molecule to rhodopsin molecule with an exponentially distributed time about some mean value (as observed, for example, for the open time of single ion-channel molecules with simple open–closed transitions in patch-clamp recordings). Along this line of thought, the amplitude and perhaps also the time course of the single-photon response should in principle vary substantially. The reason why this expected variability of the single-photon response is not observed has recently become better understood. It appears that photoactivated rhodopsin does not inactivate in a single molecular step and also that the time course of the single-photon response is not dominated by the inactivation of rhodopsin (i.e., its dominant time constant is not rhodopsin inactivation; see Section 1.10.10).

Finally, the single-photon response in cones is considerably (25–100 times) smaller than that in rods. This difference reflects a lower amplification in the transduction process in cones (with amplification defined here as the relative peak amplitude of the overall electrical signal triggered by an absorbed photon) (see Section 1.10.14). Most of the difference in sensitivity to incident light between dark-adapted rods and cones in fact comes from a difference in the

transduction amplification rather than in the photon-capturing ability, because the latter parameter is often well within a factor of 10 of each other between rods and cones. With the very small single-photon response in cones, the variance analysis described above is not useful for extracting its amplitude because the variance associated with the stochastic occurrence of quantal events is much smaller than the baseline noise in the dark current. Instead, light calibrations and cone outer-segment dimensions will have to be used for the estimate.

1.10.8 Pigment Noise

A visual-pigment molecule is composed of a protein moiety (opsin) and a covalently linked chromophore, the light-absorbing 11-*cis*-retinaldehyde (11-*cis*-retinal, also referred to as vitamin A_1 chromophore), which is a derivative of vitamin A (Wald, G., 1968; Thompson, D. A. and Gal, A., 2003; Blomhoff, R. and Blomhoff, H. K., 2006). Light acts by isomerizing 11-*cis*-retinal to all-*trans*-retinal, thereby activating the pigment. It takes substantial light energy to isomerize the pigment (Birge, R. R., 1990; Okada, D., *et al.*, 2001), so the latter is very stable in darkness. Nonetheless, simply for the fact that there are 10^8–10^9 pigment molecules in a rod (approximately tenfold fewer in cones), thermal isomerization is expected to occur spontaneously in darkness, albeit infrequently. These thermal events give rise to false signals that introduce noise to the system. Indeed, such events can be detected by suction-pipette recording (Baylor, D. A. *et al.*, 1980). In amphibian rods, the rate of spontaneous isomerization is about one event per minute per cell. Considering the large number of pigment molecules present in a cell, the corresponding rate constant is very low, about 10^{-12}–10^{-11} s^{-1} at room temperature. This gives a half-life of rhodopsin with respect to thermal isomerization of $\sim 10^3$ years at room temperature! Thus, rhodopsin is indeed very stable and ideal for the task of detecting dim light. The rate is not very different in mammalian rods, because, although the total amount of pigment per rod is about tenfold lower, the rate constant of thermal isomerization is about tenfold higher because of the difference in body temperature (room temperature versus 37 °C). Cone pigments, or at least the long-wavelength (red)-sensitive pigment with A_2 chromophore (11-*cis*-dehydroretinal), have a much higher tendency to isomerize thermally (Rieke, F. and Baylor, D. A., 2000; Kefalov, V. *et al.*, 2003). From the functional standpoint, this is not such a serious signal-to-noise problem because cones generally operate in bright light.

Another interesting difference between rod and cone pigments is that rod pigment, once formed from opsin and 11-*cis*-retinal, hardly dissociates except after isomerization of 11-*cis*-retinal to all-*trans*-retinal. Cone pigments, on the other hand, have some tendency to dissociate into opsin and 11-*cis*-retinal even in darkness, that is, without isomerization (Matsumoto, H. *et al.*, 1975; Kefalov, V. *et al.*, 2005). Consequently, a percentage of the pigment in cones appears to lack chromophore in darkness (Kefalov, V. *et al.*, 2005). Again, from the standpoint of photon capture, this may not matter much because cones function in bright light. Nonetheless, one implication of the dark dissociation of cone pigment but not of rhodopsin is that, after intense light, when rhodopsin and cone pigments are both bleached (i.e., the rod and cone opsins have dissociated from the isomerized all-*trans*-retinal), rod opsin will be able to outcompete cone opsin in acquiring free 11-*cis*-retinal recycled in the pigment epithelial cells, which is the primary site of retinoid turnover in the retina. Perhaps for this reason, cones appear to have acquired the ability of obtaining chromophore not just from the retinal pigment epithelium (the common source of 11-*cis*-retinal for both rods and cones) but also from another source apparently only available to cone cells (Mata, N. L. *et al.*, 2002), probably Müller glial cells (see also Section 1.10.10).

What good does it do to cone pigments to be dissociable in darkness? The answer lies perhaps not so much in the dissociation property itself as in the need for rapid recycling of cone pigments because they operate in bright-light conditions. This rapid recycling necessitates rapid dissociation of all-*trans*-retinal from the opsin so that the latter can quickly acquire 11-*cis*-retinal to become functional pigment again. The rapid dissociation of all-*trans*-retinal from cone opsins presumably requires a relatively open or loose chromophore-binding pocket in cone opsins. It is not unreasonable to think that such an open binding pocket unavoidably impacts the stability of the dark pigment as well, hence the dark dissociation. In other words, the molecular design for achieving rapid regeneration of bleached cone pigment may come with a price for the pigment in darkness. By the same token, rod pigment is extremely stable in darkness as discussed above, but apparently at the price of slow regeneration following a bleach.

Besides pigment noise, there is noise from the other steps of the phototransduction signaling cascade. These will be mentioned in Section 1.10.10. The functional implications of noise in light detection are discussed in a different chapter by another author (see Chapter Seeing in the Dark: Retinal Processing and Absolute Visual Threshold).

1.10.9 The cGMP-Gated, Light-Suppressible, Nonselective Cation Channel

The light-suppressible dark current entering the outer segments of rods and cones is now known to go through a nonselective cation channel that is opened (or gated) by cGMP (Fesenko, E. E. *et al.*, 1985; Yau, K.-W. and Nakatani, K., 1985b). When first discovered by Fesenko E. E. *et al.* (1985), the operation of this channel was highly surprising because, up till then, cyclic nucleotides (cAMP and cGMP) had been known (and thought) to act only indirectly on ion channels through cyclic nucleotide-dependent protein kinases. The cGMP-gated channel was thus a major discovery in the general context of ion channels. Even more importantly, the discovery provided a huge impetus to solving the phototransduction mechanism (see Section 1.10.10). Not long afterward, the discovery also helped solve the mechanism of olfactory transduction, which, remarkably, has turned out to involve an analogous signaling cascade and, in particular, a very similar cation channel (with cAMP acting as the second messenger gating the channel in this case) (Nakamura, T. and Gold, G. H., 1987). Rather atypical to ligand-gated channels, the cGMP-gated channel shows no desensitization to cGMP (the ligand). This property may be unusual, but it is functionally critical for phototransduction in rods and cones by allowing the channel to stay open and sustain a dark current in the presence of a steady concentration of free cGMP in the outer segment, and to close only in response to a decrease in the free cGMP concentration caused by light (see Section 1.10.10).

Rods and cones have molecularly distinct cGMP-gated channels, although these have broadly similar functional properties. These channels, together with the cAMP-activated channel mediating olfactory transduction in the olfactory receptor neurons of the nose, constitute the family of *c*yclic *n*ucleotide-*g*ated (CNG) channels (Finn, J. T. *et al.*, 1996; Kaupp, U. B. and Seifert, R., 2002; Craven, K. B. and Zagotta, W. N., 2006). The cGMP and cAMP designations refer only to the native ligand used by the respective cells for controlling the channel, and not to the intrinsic specific sensitivity of the channel to a particular cyclic nucleotide. Indeed, the cAMP-gated channel in olfaction is actually slightly more sensitive to cGMP than to cAMP, although cAMP is the native ligand at least in the nose (Nakamura, T. and Gold, G. H., 1987). The cGMP-gated channels in rods and cones are also sensitive to cAMP, though requiring over 100-fold higher concentrations of cAMP for the same effect.

A large amount of structure–function information is now available about the CNG channels. Briefly, this channel family comprises A (A1–A4) and B (B1 and B3; B2 does not exist in current terminology) subunits (Bradley, J. *et al.*, 2001; 2005). A-subunits can be viewed as principal subunits, and B subunits as accessory or modulatory subunits. When heterologously expressed, A1- to A3-subunits can form homomeric channels that are opened by cyclic nucleotides, but A4, as well as B1 and B3, cannot. The functional channel complex is a tetramer. The rod cGMP-gated channel is composed of three CNGA1 and one CNGB1 subunits (Weitz, D. *et al.*, 2002; Zheng, J. *et al.*, 2002; Zhong, H. *et al.*, 2002), while the cone cGMP-gated channel is reportedly composed of two CNGA3 and two CNGB3 subunits (Peng, C. *et al.*, 2004). The latter finding on the cone channel is rather surprising and perhaps best viewed as tentative, considering the fundamental difference in subunit symmetry from that of the rod channel.

The CNG channels are distant relatives of voltage-gated potassium channels (such as the Shaker K channel superfamily) with six transmembrane domains and a reentry hairpin between the fifth and sixth transmembrane domains forming part of the pore (Figure 10(a)) (for reviews, see Finn, J. T. *et al.*, 1996; Kaupp, U. B. and Seifert, R., 2002; Craven, K. B. and Zagotta, W. N., 2006). Although some of the molecular features of the voltage sensor (the so-called S4 domain) of the K channels are also present in the CNG channels (consisting of evenly spaced, positively charged amino acid residues in the fourth transmembrane domain), this sensor does not have the ability to gate CNG channels with voltage alone, that is, in the absence of cyclic nucleotide. The sensitivity of the CNG channels to cyclic nucleotides is conferred by a consensus cyclic nucleotide-binding site (similar in structure to that found in, for example, the cAMP-dependent protein kinase) situated in the cytoplasmic, C-terminal tail of the protein. With the site on each subunit binding a single cyclic nucleotide molecule, the functional channel complex therefore can bind four cyclic nucleotide molecules.

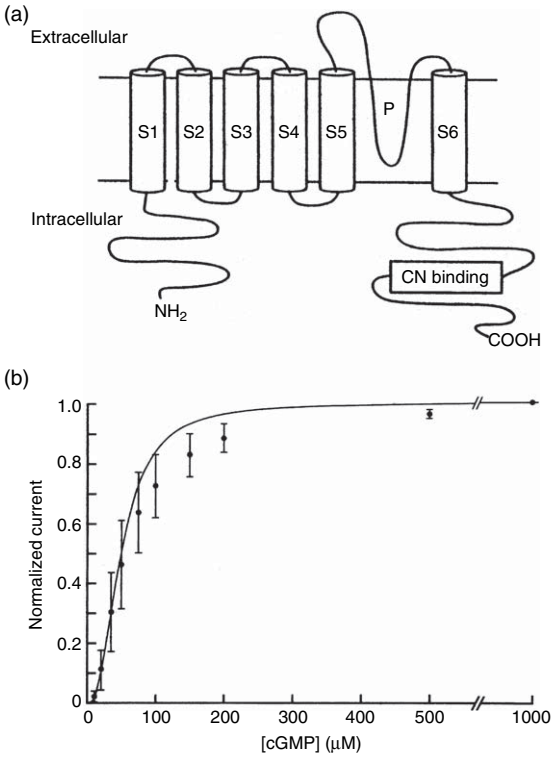

Figure 10 (a) Diagram showing the structure of one *c*yclic *n*ucleotide-*g*ated (CNG) channel subunit. P indicates pore region. "CN binding" indicates cyclic nucleotide-binding domain. (b) Dose–response relation of the rod cGMP-activated channel obtained from the truncated-rod-outer-segment preparation. Smooth curve is the Hill equation, with a coefficient of 2.4. (a) Reproduced with permission from Finn, J. T., Grunwald, M. E., and Yau, K.-W. 1996. Cyclic nucleotide-gated ion channels: an extended family with diverse functions. Annu. Rev. Physiol. 58, 395–426. (b) Reproduced with permission from Nakatani, K. and Yau, K.-W. 1988c. Guanosine 3′,5′-cyclic monophosphate-activated conductance studied in a truncated rod outer segment of the toad. J. Physiol. 731–753.

The channel complex has a very low or negligible probability of opening in the absence of cyclic nucleotide (depending on the particular complex), but the open probability increases dramatically when all, or nearly all, of the four sites are occupied (Picones, A. and Korenbrot, J. I., 1995; Ruiz, M. L. and Karpen, J. W., 1997). These facts explain the observed dose–response relation between channel opening and cyclic nucleotide concentration. For the native rod cGMP channel studied with excised membrane patches from the rod outer segment or with a truncated rod outer segment, this relation has a Hill coefficient of 2–3 (Figure 10(b); Yau, K.-W. and Nakatani, K., 1985b; Nakatani, K. and Yau, K.-W. 1988c). The same is true for the cone cGMP-gated channel (Haynes, L. W. and Yau, K.-W., 1985). The $K_{1/2}$ of activation is around 50 μM cGMP for both the rod and cone channels. There are some variations among studies in the Hill coefficient and the $K_{1/2}$ value for the rod channel (and probably the cone channel as well, although this channel has not been studied as extensively). This variability may be attributed to the channel population under study not being homogeneous, such as phosphorylated versus unphosphorylated (Gordon, S. E. *et al.*, 1992; Molokanova, E. *et al.*, 1997), and so on.

With the truncated-photoreceptor preparation (Figure 3(c)), it is possible to estimate the percentage of cGMP-gated channels that are open in darkness. It turns out that only of the order of 1% of the channels are open in darkness whether in the rod or in the cone, and, of course, this percentage only decreases in the light (Yau, K.-W. and Nakatani, K., 1985b; Nakatani, K. and Yau, K.-W., 1986; 1988c). Because cGMP binds and unbinds randomly and continuously, different channels open and close over time; however, the percentage of open channels stays at ~1% at a given time instant. Why are the channels present in such excess? The answer lies in the fact that, like any binding reaction, the approach to saturated binding is asymptotic (Figure 10(b)). Thus, if there were only as many cGMP-gated channels present on the membrane as the cell needs for sustaining a given dark current, a very high cGMP concentration would be necessary in order for all channels to be open. This scenario would conceivably introduce two problems. One is that a large decrease in free cGMP concentration would have to occur in the light in order for any substantial percentage of the open channels to close. The other is that cGMP is an important signaling messenger in cells, so it is probably inappropriate for the cell to maintain its free concentration beyond a certain level. Moreover, because the steady cGMP level represents a balance between steady synthesis and hydrolysis in darkness, a high steady cGMP concentration would also entail a high rate of steady hydrolysis, which is wasteful. In principle, to offset this, if the channel had a much lower $K_{1/2}$ value (i.e., a higher apparent affinity for cGMP), the required free cGMP concentration could be lowered considerably. However, a much lower $K_{1/2}$ would imply that the cGMP already bound to the channels at light onset would not necessarily dissociate rapidly even when the cytoplasmic free cGMP has decreased, thus making

phototransduction a slow process (Yau, K.-W. and Baylor, D. A., 1989; Yau, K.-W., 1994).

From the ~1% of channels open in darkness, and the dose–response relation mentioned above, the free cGMP concentration in the outer segment can be estimated to be around one to a few micromolar in darkness (Yau, K.-W. and Nakatani, K., 1985b; Nakatani, K. and Yau, K.-W., 1988c). The measured total concentration of cGMP in the outer segment is about 60 μM (Kilbride, P. and Ebrey, T. G., 1979). Thus, most of the cGMP is tightly bound, though not to the channels (see Section 1.10.10).

The cGMP-gated channel is a nonselective cation channel (Yau, K.-W. and Nakatani, K., 1984a; Hodgkin, A. L. *et al.*, 1985), passing not only Na^+ and K^+, but also Ca^{2+}, and perhaps Mg^{2+} (Yau, K.-W. and Nakatani, K., 1985a; Nakatani, K. and Yau, K.-W., 1988b; but see Chen, C. *et al.*, 2003). For the rod channel, 75–80% of the inward dark current at the outer segment is carried by Na^+, and about 15% by Ca^{2+} (Yau, K.-W. and Nakatani, K., 1985a; Nakatani, K. and Yau, K.-W., 1988b). For the cone channel, the percentage of dark current carried by Ca^{2+} may be as much as 30% (Perry, R. J. and McNaughton, P. A., 1991; Ohyama, T. *et al.*, 2000). There is probably not much K^+ efflux through the channel in darkness, but the exact amount is not known. In steady state in darkness, the Na^+ influx is balanced by an equal efflux via the Na^+ pump situated in the inner segment/cell body. The steady Ca^{2+} influx is balanced by an equal efflux at the outer segment via a Na^+/Ca^{2+} exchange mechanism that employs the inward-directing Na^+ electrochemical gradient to extrude Ca^{2+} (Yau, K.-W. and Nakatani, K., 1984b, 1985a; Nakatani, K. and Yau, K.-W., 1988c). Unlike the Na^+/Ca^{2+} exchanger found in most other tissues, the one on retinal photoreceptors also involves a K^+ efflux (Cervetto, L., *et al.*, 1989). Thus, it is really a $Na^+/Ca^{2+},K^+$ exchanger, with a stoichiometry of four Na^+ entering the cell for one Ca^{2+} and one K^+ leaving the cell, giving one net possible charge entering the cell for each Ca^{2+} leaving (Yau, K.-W. and Nakatani, K., 1984b; Cervetto *et al.*, 1989). The implication is that the outward-directing K^+ electrochemical gradient also helps the extrusion of Ca^{2+}. This stoichiometry endows the exchanger with the capability of pumping down the intracellular Ca^{2+} concentration to a very low level, in principle as low as 2 nM (Cervetto *et al.*, 1989), without even the consumption of ATP. The net entry of one positive charge per exchange cycle means that the exchanger is electrogenic, producing an inward membrane current that can be measured (Yau, K.-W. and Nakatani, K., 1984b). This electrogenicity has provided a great impetus to solving the phototransduction mechanism, by providing a convenient monitor of the intracellular free Ca^{2+} concentration (Yau, K.-W. and Nakatani, K., 1985a) (see Section 1.10.10). The steady influx of Na^+ through the cGMP-gated channels and through the $Na^+/Ca^{2+},K^+$ exchanger in darkness necessitates high activity of the Na^+ pump to maintain the Na^+ electrochemical gradient and imposes a heavy metabolic load on the rods and cones. Probably for this reason, there is a high concentration of mitochondria in the inner segment immediately next to the outer segment (Cohen, A. I., 1987; Dowling, J. E., 1987). Incidentally, on a per-gram basis, the retina is a tissue with one of the highest oxygen consumptions in the body – more than that of the brain (Anderson, B. and Saltzman, H. A., 1964; Ames, A., III, 1992).

One interesting property of the rod and cone cGMP-gated channels (and a property of CNG channels in general) is that, apart from being permeable to divalent cations (Ca^{2+} and Mg^{2+}), these channels are subject to partial blockage by them (Haynes, L. W. and Yau, K.-W., 1985; Haynes, L. W. *et al.*, 1986). One consequence of this (kinetically fast) blockage is that, under physiological ionic conditions, the channels have a very small effective single-channel current, which is in the femtoampere (10^{-15} A) instead of picoampere (10^{-12} A) range after low-pass filtering by the membrane time constant (Detwiler, P. B. *et al.*, 1982; Gray, P. and Attwell, D., 1985). This small effective single-channel current means that, for a given dark current (~20–40 pA), many more open channels are recruited (estimated to be 10^4, out of a total channel population of ~10^6 on the outer segment of rods and cones) (Yau, K.-W., 1994). The recruitment of a large number of effectively small open channels instead of a small number of large open channels reduces the quantization noise associated with the random opening and closing of channels in darkness and at the same time increases the reliability of the light signal by reducing its quantization as well (Yau, K.-W. and Baylor, D. A., 1989). With the background noise and the reliability of the signal each improved by the square root of the multiplication factor (100-fold) for the number of underlying channels, the overall signal-to-noise ratio of the light signal is effectively improved by as much as 100-fold. The blockage by external divalent cations also converts a roughly linear current–voltage relation of the cGMP-gated channel in the absence of

divalent cations into one that is highly rectifying. For the rod channel, the resulting current–voltage relation is such that the outward current rapidly increases with increasingly depolarized potentials (outward rectification), but the inward current is almost constant at voltages more negative than −35 mM, which is the physiological range of the membrane potential (Baylor, D. A. and Nunn, B. J., 1986). This flat current–voltage relation (like a constant-current generator) at physiological potentials helps the cell count/report absorbed photons with fidelity. The cone channel is, like the rod channel, outward-rectifying at positive potentials but is inward-rectifying at negative potentials (i.e., increasing inward current with increasing hyperpolarization) (Haynes, L. W. and Yau, K.-W., 1985). The functional benefit of the inward rectification at negative voltages is unclear; it may just be an inevitable feature associated with the higher permeability of the cone channel to divalent cations.

1.10.10 Phototransduction Cascade

The mechanism of phototransduction was a topic of intense dispute in the 1970s and early 1980s, centered on whether Ca^{2+} or cGMP was the true second messenger for the process, and in what manner. These competing ideas had come to be referred to as the Ca^{2+} hypothesis and the cGMP hypothesis, respectively (Miller, W. H., 1981). The dispute was finally settled in the mid-1980s, with the revelation that cGMP is the messenger for transduction and Ca^{2+} the messenger for light adaptation. The key findings leading to this resolution were the discoveries of the cGMP-gated channel (Fesenko, E. E. *et al.*, 1985; Yau, K.-W. and Nakatani, K., 1985b; Nakatani, K. and Yau, K.-W., 1988c) and of a light-induced decrease in the free Ca^{2+} concentration of the outer segment as revealed by the electrogenic $Na^+/Ca^{2+}/K^+$ exchanger (Yau, K.-W. and Nakatani, K., 1985a; Nakatani, K. and Yau, K.-W., 1988b), both entities described in the previous section. The details of the current picture of phototransduction are described below (Figure 11) (Burns, M. E. and Baylor, D. A., 2001; Arshavsky, V. Y. *et al.*, 2002; Chen, C.-K., 2005; Fu, Y. and Yau, K.-W., 2006). The tortuous path leading to the eventual solution of the problem can be found in a personal account (Yau, K.-W., 1994). In what follows, rod phototransduction is the basis for discussion because much more is known about it than about cone transduction. Qualitatively speaking, however, rod and cone transductions are very similar, although most proteins involved have distinct rod and cone isoforms. Some specific and important differences between rod and cone transductions will be briefly described in Section 1.10.14.

As mentioned earlier, a visual pigment is made up of opsin, which is a seven-transmembrane-helix protein and prototypical G-protein-coupled receptor (GPCR), covalently linked to a chromophore, which is 11-*cis*-retinal. Photoisomerization of 11-*cis*-retinal to all-*trans*-retinal unleashes spontaneous conformational changes in the opsin, leading eventually to the formation of the active intermediate, Meta II, within about 1 ms (Kandori, H. *et al.*, 2001). Essentially by diffusion on the disk membrane, Meta II collides and activates (Lamb, T. D., 1994; Calvert, P. D. *et al.*, 2000; Leskov, I. B. *et al.*, 2000) the peripheral membrane protein transducin, a heterotrimeric G protein (G_T, composed of α-, β-, and γ-subunits) with distinct isoforms in rod and cone photoreceptors. Meta II acts by catalyzing the exchange of GTP for GDP in the nucleotide-binding pocket of the α-subunit, $G_{T\alpha}$, and the consequent dissociation of $G_{T\alpha}GTP$ from $G_{T\beta\gamma}G_{T\alpha}GTP$ in turn stimulates a cGMP-phosphodiesterase (cGMP-PDE), another peripheral membrane protein, to increase the hydrolysis of cGMP. This enzyme is composed of two catalytic subunits (PDE$\alpha\beta$ in rods or two PDEα' in cones) and two inhibitory subunits (two PDEγ in rods and two PDEγ' in cones). $G_{T\alpha}GTP$ acts by binding to the inhibitory subunit (with a stoichiometry of one $G_{T\alpha}GTP$ for one PDEγ) and removing its inhibitory influence on a catalytic subunit. The resulting increase in PDE activity lowers the cytoplasmic level of free cGMP, and the cGMP-gated channels therefore close and produce a membrane hyperpolarization as the light response. The high amplification of phototransduction in rods described earlier, which allows these cells to signal single absorbed photons, arises in part from the fact that each rhodopsin molecule has a sufficiently long-lasting Meta-II state before inactivation sets in (see below) to be able to activate successively a substantial number of transducin molecules. Over the years, however, the estimate for the number of transducin molecules activated by one Meta-II molecule during the response has dwindled from an initial high of $\sim 10^3$ to a current number of perhaps 20 in a mouse rod (Krispel, C. M. *et al.*, 2006), still a substantial number nonetheless.

A very useful mathematical formulation, called the Lamb–Pugh model, was developed that very accurately describes the rising phase of the light response (Lamb, T. D. and Pugh, E. N., 1992).

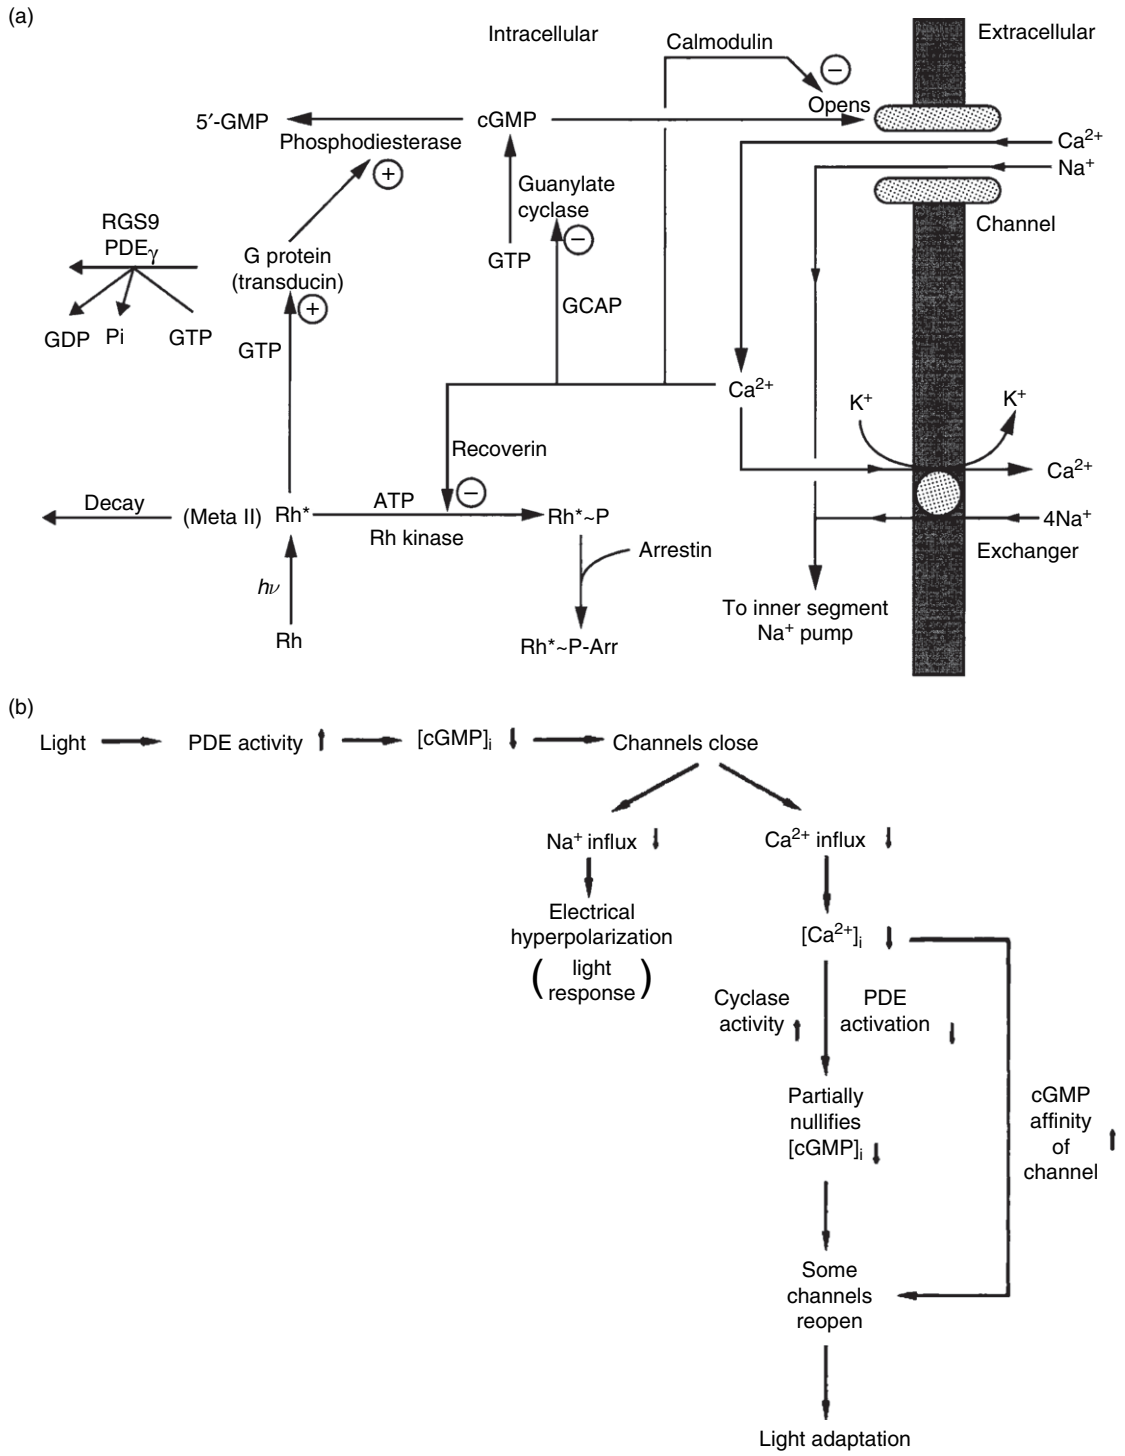

Figure 11 (a) Phototransduction mechanism underlying the light response in rods. GCAP, guanylate cyclase-activating protein; $h\nu$, photon; Rh, rhodopsin; Rh*, photoactivated rhodopsin; Rh*~P, phosphorylated form of rhodopsin; RGS9, regulator of G-protein-signaling isoform 9; PGE_γ, inhibitory (γ) subunit of the phosphodiesterase; +, stimulation or positive modulation; –, inhibition or negative modulation. In addition to RGS9, two other proteins not shown here (RG9P and $G_\beta 5$, see text) are also part of the GTPase-activating protein (GAP) complex. (b) Flow chart showing the sequence of events triggered by light in phototransduction. (a) Adapted with permission from Koutalos, Y. and Yau, K.-W. 1996. Regulation of light sensitivity in retinal rods. Trends in Neurosci. 19, 73–81. (b) Reproduced with permission from Yau, K.-W. 1994. Phototransduction mechanism in retinal rods and cones. The Friedenwald Lecture. Invest. Ophthalmol. Vis. Sci. 35, 10–32.

Ignoring the inactivation steps (see below) and making simplifying assumptions that are valid under most circumstances, the model arrives at the following Gaussian function, with a single free parameter, A, to describe the rising phase of the flash response:

$$F(t) = \exp\left(\frac{-\phi A(t - t_{\text{eff}})^2}{2}\right)$$

where Φ is the flash intensity, A the free parameter called the amplification constant of transduction, t time, and t_{eff} an effective delay time that lumps together several short delays in transduction. Once t_{eff} and A are appropriately chosen, the same value of A can predict a whole family of responses to flashes of different intensities. The parameter A embodies (and is indeed the multiplicative product of) the rate of PDE activation by a photon, the rate constant of cGMP hydrolysis by PDE, and the Hill coefficient of channel activation by cGMP. The above equation is equally applicable to single-cell recordings as to ERG recordings (Breton, M. E. *et al.*, 1994). It is especially useful for comparing the amplification gains of rods and cones from different animal species and also analyzing the light responses of rods and cones in disease conditions of humans or animal models.

The termination of phototransduction requires the inactivation of all active species in the signaling cascade (Burns, M. E. and Baylor, D. A., 2001; Arshavsky, V. Y. *et al.*, 2002; Chen, C.-K., 2005; Fu, Y. and Yau, K.-W., 2006). The shutoff of Meta II involves first the phosphorylation of multiple serine/threonine residues on its cytoplasmic C-terminus by a specific kinase (pigment kinase, which is a member of the GPCR kinase, or GRK, family; rhodopsin kinase is GRK1; see also Section 1.10.14), which partially stops its activity (Chen, J. *et al.*, 1995; Chen, C.-K. *et al.*, 1999; Mendez, A. *et al.*, 2000). This is followed by the binding of a protein called arrestin, also to its C-terminus, to cap the activity of Meta II (Xu, J. *et al.*, 1997). The downstream active species, $G_{T\alpha}GTP$, self-deactivates by its intrinsic GTPase activity, which hydrolyzes the bound GTP to GDP and consequently returns to its inactive $G_{T\alpha}GDP$ state to be ready for activation again after reassociation with $G_{T\beta\gamma}$. The GTPase activity of $G_{T\alpha}GTP$ is weak by itself, but in the native cell, this is enhanced by PDEγ, its substrate, together with a GTPase-activating protein (GAP) complex consisting of RGS9 (regulator of G-protein-signaling isoform 9), $G_{\beta 5}$ (another G protein β-subunit or a G protein β-subunit-like protein), and R9AP (RGS9-anchoring protein) (Tsang, S. H. *et al.*, 1998; Chen, C.-K. *et al.*, 2000; Krispel, C. M. *et al.*, 2003; Keresztes, G. *et al.*, 2004). When transducin deactivates, so does PDE by restoration of the inhibitory activity of PDEγ. The cytoplasmic free cGMP concentration then returns to the dark level because of the ongoing activity of the photoreceptor guanylate cyclase (GC), a cGMP-synthesizing enzyme. The closed cGMP-gated channels thus reopen. In short, as mentioned in a previous section, there is steady cGMP synthesis and hydrolysis in darkness, and a light flash simply transiently tips the balance toward hydrolysis (Hodgkin, A. L. and Nunn, B. J., 1988).

How is the pigment rejuvenated? The inactivated Meta II eventually decays to the intrinsically inactive Meta-III state, which then dissociates into opsin and free all-*trans*-retinal, a process called bleaching because neither component absorbs in the visible spectrum (Wald, G., 1968). Along the way, the opsin also loses its bound arrestin and is dephosphorylated by a generic kinase (protein phosphatase 2A). As for the all-*trans*-retinal, it is reduced to all-*trans*-retinol (-ol stands for alcohol) in the photoreceptor. All-*trans*-retinol diffuses, perhaps helped by the carrier protein IRBP (interphotoreceptor-matrix retinal-binding protein), from the photoreceptor to the pigment epithelial cell, where it is converted into all-*trans*-retinylester, then reisomerized by the isomerohydrolase enzyme RPE65 to 11-*cis*-retinol, and dehydrogenated to 11-*cis*-retinal before returning to the photoreceptor and recombining spontaneously with opsin to form the holopigment once more (Lamb, T. D. and Pugh, E. N., 2004; Jin, M. *et al.*, 2005; Moiseyev, G. *et al.*, 2005; Travis, G. H. *et al.*, 2006). Recently, it has become known that the cone-dominant retinas also possess a chromophore-regeneration mechanism, apparently available specifically to the cones (Mata, N. L. *et al.*, 2002). Presumably, this pathway takes place in the Müller cells, which is known to release the chromophore as 11-*cis*-retinol (Das, S. R. *et al.*, 1992). Cones are also known to be able to take up 11-*cis*-retinol directly, not necessarily just at the outer segment but also at other parts of the cell, and convert it to 11-*cis*-retinal for pigment regeneration (Jones, G. J. *et al.*, 1989). As pointed out in Section 1.10.8, this additional regeneration mechanism may be important in bright light, when cone pigment has to compete with rhodopsin for free 11-*cis*-retinal from the pigment epithelium but, being dissociable, may be outcompeted by the nondissociable rhodopsin acting as a huge sink of 11-*cis*-retinal (Kefalov, V. *et al.*, 2005; Travis, G. H., 2005).

Ca^{2+} has a critical role in active adaptation of the rod or cone to light. As mentioned in Section 1.10.9, there is in darkness a steady Ca^{2+} influx via the cGMP-gated channels and an equal Ca^{2+} efflux via a $Na^+/Ca^{2+},K^+$ exchanger both on the plasma membrane of the outer segment. In the light, the closure of CNG channels stops the Ca^{2+} influx, but the Ca^{2+} efflux through the exchanger continues, draining the free Ca^{2+} concentration in the outer segment. This Ca^{2+} decrease triggers multiple negative-feedback pathways to regulate phototransduction, producing active adaptation to light (Figure 11) (Koutalos, Y. and Yau, K.-W., 1996; Pugh, E. N. *et al.*, 1999). Perhaps the most convincing evidence for Ca^{2+}'s key role in adaptation is that, if Ca^{2+} in the rod outer segment is prevented from changing in the light, all signs of active adaptation disappear (Matthews, H. R. *et al.*, 1988; Nakatani, K. and Yau, K.-W., 1988a). One negative-feedback pathway triggered by the light-induced decrease in Ca^{2+} acts on the GC to enhance its activity, via Ca^{2+}-binding proteins called GC-activating proteins (GCAPs) (Koch, K.-W. and Stryer, L., 1988; Mendez, A. *et al.*, 2001; Burns, M. E. *et al.*, 2002). With no Ca^{2+} bound, the GCAPs facilitate the GC activity; with Ca^{2+} bound, however, the facilitating action of the GCAPs decreases. A second feedback pathway is thought to act, via a Ca^{2+}-binding protein called recoverin (also called S-modulin), on the pigment kinase that phosphorylates Meta II (Kawamura, S. and Murakami, M., 1991; Kawamura, S., 1993; Makino, C. L. *et al.*, 2004). It ultimately scales down the amount of PDE activity activated by a Meta-II molecule, presumably by speeding the phosphorylation of Meta II. A third pathway acts on the cGMP-gated channel, perhaps via Ca^{2+}-calmodulin, which binds to the channel and inhibits its opening by cGMP (Hsu, Y. T. and Molday, R. S., 1993; Chen, T.-Y. *et al.*, 1994; Nakatani, K. *et al.*, 1995). The binding site for the modulator on the rod channel has been localized to the cytoplasmic N-terminus of the single CNGB1 subunit in the channel complex (Grunwald, M. E. *et al.*, 1998; Weitz, D. *et al.*, 1998). Like calmodulin, GCAPs and recoverin are EF-hand-type Ca^{2+}-binding proteins. Of the three Ca^{2+}-mediated regulatory pathways, the one acting on GC is the most important for low and intermediate light levels (Koutalos, Y. *et al.*, 1995; Burns, M. E. *et al.*, 2002), above which the one decreasing PDE activity begins to kick in, becoming increasingly important with still higher light levels (Koutalos, Y. *et al.*, 1995). The regulatory pathway for the gating of the channel, on the other hand, is weak and of minimal importance. The same Ca^{2+} feedbacks exist in cones (Tamura, T. *et al.*, 1991), although the role of the feedback on channel gating and the identity of the Ca^{2+}-binding protein involved are still murky (Rebrik, T. I. and Korenbrot, J. I., 1998). Because cones adapt so much more effectively to light than do rods, there must be some quantitative differences between the two, albeit involving similar mechanisms.

Figure 11(b) provides a flowchart of the sequence of events triggered by light in the photoreceptor.

With the phototransduction mechanism now well understood, comments to several points raised earlier in this chapter are in order.

First, it was mentioned in Section 1.10.8 that there is in darkness a low level of spontaneous pigment isomerization activity, which introduces noise to the light-detection pathway. In addition to this so-called discrete noise (referring to the spontaneous quantum bumps, which are sporadic but large), there is a continuous noise that represents a steady rumble of the dark current (Baylor, D. A. *et al.*, 1980). In principle, this noise can originate either from the synthesizing or from the hydrolytic pathway of cGMP. It now appears that, at least in rods, most of the continuous noise comes from the latter, namely, constitutive rocking of the inhibitory γ-subunits on the catalytic $\alpha\beta$-subunits of the PDE, presumably giving rise to the basal activity of the enzyme (Rieke, F. and Baylor, D. A., 1996). Whether there is, additionally, constitutive transducin activity is still unclear. Nor is it clear whether the basal GC activity is associated with negligible noise. With respect to the cGMP-gated channel, because it has effectively a very small single-channel conductance (owing to the blockage by divalent cations mentioned in Section 1.10.9), the dark current associated with the open channels indeed has low noise, at least after low-pass filtering by the membrane time constant. Recently, it is reported that the PDE in cones is also noisy (Holcman, D. and Korenbrot, J. I., 2005).

Second, it was mentioned in Section 1.10.9 that only ~1% of the total cGMP content in the outer segment is free (Yau, K.-W. and Nakatani, K., 1985b; Nakatani, K. and Yau, K.-W., 1988c). Most of the cGMP turns out to be tightly bound to none other than noncatalytic sites on the catalytic subunits of the PDE, PDE$\alpha\beta$ (Arshavsky, V. Y. *et al.*, 1992). With a holo-PDE concentration of about 30 μM in the rod outer segment, and the PDEα and PDEβ each known to have one noncatalytic cGMP-binding site, just about all of the ~60 μM total cGMP is bound and not freely exchangeable with the cytosolic

cGMP, which is the pool relevant to channel gating. Apparently, the cGMP bound to PDEα and PDEβ acts allosterically on the respective catalytic sites to modulate the hydrolytic activity of the enzyme; the bound cGMP only comes off when the cytosolic cGMP decreases drastically in the light (Arshavsky, V. Y. *et al.*, 1992). Because the free pool of cGMP is very small, and the tight cGMP-binding sites on the PDE do not really function as a buffer, the large excess of unopen cGMP-gated channels in darkness present a potentially unstable situation. Any accidental metabolic surge in cGMP level will greatly increase the number of open channels (owing to the high Hill coefficient of channel activation) and flood the cell with Na^+ and Ca^{2+}, no doubt deleterious to the cell. From this standpoint, the negative-feedback pathways triggered by Ca^{2+} are not only important in the light, but they are equally important in darkness by stabilizing the cGMP level, safeguarding against such dangerous metabolic fluctuations and also helping signaling by reducing background noise (Nakatani, K. and Yau, K.-W., 1988b; Yau, K.-W., 1994; Burns, M. E. *et al.*, 2002).

Third, it was mentioned in Section 1.10.7 that the single-photon response is remarkably stereotypic from flash to flash. Long a puzzle, this observation has recently been intensively studied (Rieke, F. and Baylor, D. A., 1998; Whitlock, G. G. and Lamb, T. D., 1999; Field, G. D. and Rieke, F., 2002; Hamer, R. D. *et al.*, 2003) and may now be finally solved. The constancy of the single-photon response has two aspects: amplitude and duration. With respect to duration, it was long debated whether the decay of the response is dictated by the inactivation of rhodopsin or the deactivation of transducin ($G_{T\alpha}GTP$). It now appears that, at least in the mouse, the deactivation of transducin is in fact the dominant time constant (Krispel, C. M. *et al.*, 2006). Because each rhodopsin molecule activates many (estimated to be ~20) transducin molecules, the averaging over the decays of many transducin molecules can account for the constancy of the decay of the single-photon response (Krispel, C. M. *et al.*, 2006). As for the amplitude, rhodopsin decay is important. Here again, the multiphosphorylation of an active rhodopsin molecule (Mendez, A. *et al.*, 2000; Doan, T. *et al.*, 2006) may provide sufficient averaging to give an overall rather constant single-photon response amplitude.

And fourth, it was mentioned in Kinetics of the Dim-Flash Response that the kinetics of the dim-flash response can be described by a series of four linear stages. Based on the aforementioned, these stages can be schematically assigned as rhodopsin, transducin, phosphodoesterase, and cGMP-gated channel as shown in Figure 6(b). Again, the scheme is symbolic, not meant to be exact kinetically.

Several additional comments are in order. First of all, GPCRs, including visual pigments, have long been implicitly assumed to be monomers. This idea has begun to change in recent years when there is evidence that some synaptic metabotropic receptors are actually dimers (Kubo, Y. and Tateyama, M., 2005). The same appears true for some sensory GPCRs, such as taste receptors (Nelson, G. *et al.*, 2002; Xu, H. *et al.*, 2004). The idea of a monomer held firm for visual pigments, perhaps for the reason that all it takes is one photon to elicit a response. However, the tide is slowly changing even for vision, with some data suggesting that rhodopsin may be a dimer at least under some experimental conditions (Fotiadis, D. *et al.*, 2003; 2006). Strictly speaking, there is no incompatibility between the notion of a rhodopsin dimer and the single-photon response (or, more aptly, a linearity at the foot of the intensity–response relation of the photoreceptor) because all it may require for the rhodopsin dimer to be active is having one or the other rhodopsin monomer member in the dimer to capture a photon and isomerize. The unisomerized rhodopsin in the dimer may function purely as a passive partner, helping out but not physically catalyzing the GTP–GDP exchange.

Also, although the phototransduction process is extremely well understood, there are certain subtleties/-phenomena that remain to be fathomed. For example, although it is now firmly established that a simple imbalance between Ca^{2+} influx and efflux leads to a decline in the free Ca^{2+} concentration in the outer segment in the light, it appears that, under conditions of intense light, there may also be a transient release of Ca^{2+} into the cytosol from binding sites in the outer segment (Matthews, H. R. and Fain, G. L., 2001; 2002; 2003; Cilluffo, M. C. *et al.*, 2004; Leung, Y. T. *et al.*, 2006). The significance of this Ca^{2+} release is still far from clear. Another interesting observation is that mutant zebrafish cones with no functional transducin still have a small ability to produce a transient decrease in the inward current when illuminated with intense light (Brockerhoff, S. E. *et al.*, 2003). This latter point merits further investigation.

Finally, it is fair to say that phototransduction in rods and cones (especially rods) is by far the best-understood G-protein-mediated signaling pathway in the body. In fact, the advances in this field have often been used for understanding other G-protein signaling pathways. For

example, the high amplification of the rod transduction pathway – namely, a single active GPCR molecule in turn would activate a large number of downstream G-protein molecules – has been widely considered to be a dogma that applies to G-protein signaling in general. However, this generalization may not be too valid. In particular, recent work has indicated that an odorant receptor in the olfactory system, upon becoming active by binding a cognate ligand, has a very low probability of activating even a single G-protein molecule downstream (Bhandawat, V. *et al.*, 2005). Thus, most binding events are inconsequential. The reason is simple – namely, the ligand typically stays on the receptor for such a brief period that the receptor complex has scarcely little opportunity to encounter and activate even one G-protein molecule. Also, phosphorylation is unlikely the canonical deactivation mechanism for odorant receptors at the level of single-odorant-molecule binding, except possibly in the case of intense and prolonged stimulation (Bhandawat, V. *et al.*, 2005). Phototransduction is unique in that a photon disappears once absorbed by a pigment molecule. At the same time, the active Meta-II state of the rod or cone pigment remains essentially active continuously until inactivation by phosphorylation and arrestin-binding (the actual decay of Meta II to inactive Meta III is slow by comparison). With too little known quantitatively about the other GPCR pathways besides olfaction at present, it is too early to tell what (though most likely low) percentage of these pathways share the high amplification found in vision.

1.10.11 Background-Light Adaptation

Background-light adaptation is adaptation of the photoreceptor to a steady light – light that induces a significant response but not so bright that a substantial fraction of the pigment on the cell is bleached. The manifestation of background-light adaptation is a relaxation of the response to a steady light from a transient peak to a lower level soon after the onset of light (Figure 5(a)). As mentioned in Section 1.10.4, the step intensity–response relation reflects the development of background adaptation with time. At very early times after light onset, little or no adaptation is evident, with the instantaneous intensity–response relation following closely the saturating exponential function introduced in Section 1.10.4. At the transient peak of the response, however, the relation already deviates from this function, and it becomes progressively less steep at later times. At the plateau level, the relation shows a slow logarithmic rise (Nakatani, K. *et al.*, 1991).

A standard characterization of background-light adaptation is obtained by superposing incremental flashes on a steady background light in what is often called an increment-threshold experiment. In the presence of background light, the responses to incremental flashes show both a lower sensitivity and a shorter time-to-peak than those in darkness (i.e., without background light), with the shorter time-to-peak reflecting the increase in dominance of the inactivation of the response, which cuts into the rising phase at progressively earlier times (Baylor, D. A. *et al.*, 1979a; 1980). The dependence of flash sensitivity on background-light intensity is well described by the Weber–Fechner relation, $S_F = S_F^D I_o/(I_B + I_o)$, where S_F^D is flash sensitivity in the absence of background light, S_F flash sensitivity in the presence of background light with intensity I_B, and I_o a constant corresponding to the value of I_B that reduces S_F^D by half (Figure 12). This relation says that, for large I_B, $S_F \propto I_B^{-1}$. In vision, the significance of the $S_F \propto I_B^{-1}$ relation is that it allows the contrast sensitivity (i.e., the perception of light–dark contrast) to be independent of the ambient light intensity (Shapley, R. and Enroth-Cugell, C., 1984).

Mathematically, the plot of incremental flash sensitivity (the reciprocal of threshold) against background-light intensity is (approximately, by assuming no

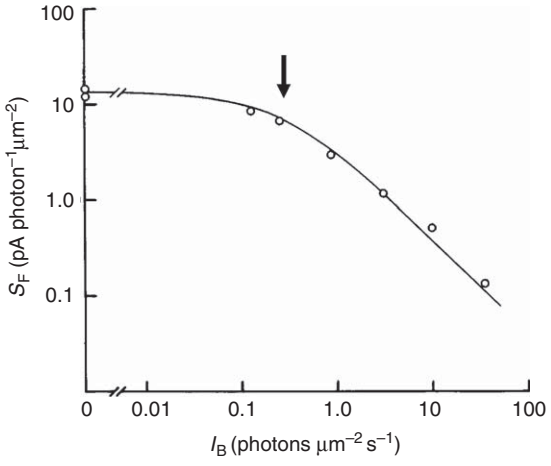

Figure 12 Incremental-flash-on-background-light experiment from a toad rod. Plot shows the dependence of flash sensitivity on background light intensity. Smooth curve is $S_F \propto 1/(I_B + I_o)$, with $I_o = 0.28$ photons (500 nm) μm^{-2} s^{-1} (arrow). Reproduced with permission from Baylor, D. J. A., Matthews, G., and Yau, K.-W. 1980. Two components of electrical dark noise in toad retinal rod outer segments. J. Physiol. 309, 591–621.

change in kinetics) nothing more than a plot of the slope of the step intensity–response relation at the plateau of the response against the steady-light intensity. Thus, the derivative of the saturating exponential function, $[1-\exp(-I_S/\rho)]$, introduced in Section 1.10.4 has the form $\exp(-I_S/\rho)$, which indeed describes the sensitivity-versus-background-intensity relation in the case of no active background adaptation (Matthews, H. R. *et al.*, 1988). Conversely, the integrated form of the Weber–Fechner relation, $\log_e(I+I_o)$ should fit the step intensity–response relation in the plateau phase of the response, which, as pointed out earlier, is roughly the case as well (Nakatani, K. *et al.*, 1991).

Like the Michaelis equation, the Weber–Fechner relation is mathematically simple, but, as in the case of the Michaelis equation, this just happens to be an approximately good fit. The underlying cellular mechanisms that give rise to the experimental observations are in fact quite complex, involving multiple active negative-feedback mechanisms mediated by a decrease in intracellular Ca^{2+} concentration during steady light, together with passive mechanisms such as the progressive saturation of the response and the basal phosphodiesterase activity in the presence of steady background light being already much higher than in darkness (Tamura, T. *et al.*, 1991; Koutalos, Y. *et al.*, 1995; Nikonov, S. *et al.*, 2000).

It had been thought for a long time that mammalian rods, unlike amphibian rods, do not adapt to background light. However, this is now known not to be the case (Tamura, T. *et al.*, 1989; Nakatani, K. *et al.*, 1991; Matthews, H. R., 1991; Tamura, T. *et al.*, 1991). Indeed, as a first approximation, mammalian and amphibian rods behave rather similarly (Nakatani, K. *et al.*, 1991). Moreover, the adaptation behavior of rods of the bush baby (galago), a strictly nocturnal primate, is very similar to that of the rods of the rhesus monkey, a diurnal primate (Tamura, T. *et al.*, 1991). Thus, it is as if the performance of rods were already optimized, and, when a natural habitat involves a broader range of light intensities, an animal simply adds cones of various extents to their retina. Finally, cones adapt to background light much more dramatically than rods, but the trigger is still Ca^{2+} (Nakatani, K. and Yau, K.-W., 1988a; Matthews, H. R. *et al.*, 1990).

1.10.12 Bleaching Adaptation

Bleaching adaptation is the desensitization that occurs in photoreceptors after a significant fraction of their pigment has been bleached by bright light. The physiological changes in photoreceptors induced by bleaching adaptation closely resemble those caused by background adaptation, discussed in Section 1.10.11 (Blakemore, C. B. and Rushton W. A. 1965; Cornwall, M. C. *et al.*, 1990). The bleaching of visual pigment by light is one mechanism by which photoreceptors change their sensitivity to bright illumination. During bleaching adaptation, the reduced level of photopigment decreases the probability of photon absorption, thus lowering photoreceptor sensitivity and increasing the range of light intensities to which the cell can respond. This loss of quantum catch is especially important for cones, which remain responsive in light bright enough to bleach up to 10^6 pigment molecules s^{-1} (Schnapf, J. L. *et al.*, 1990). Rods, in contrast, saturate in relatively dim backgrounds of less than 15 000 photons $rod^{-1}\,s^{-1}$ (Williams, T. P. *et al.*, 1998). Exposure of rods to still brighter light triggers another form of adaptation associated with the redistributions of transducin and arrestin in the photoreceptor that reduce the overall activity of the phototransduction cascade (see below).

An important feature of bleaching adaptation is that the observed decrease in sensitivity is much greater than would be expected simply from the decrease in the probability of photon capture due to reduced pigment content, either in situ in the retina (Campbell, F. W. and Rushton, W. A., 1955) or in isolated photoreceptors (Pepperberg, D. R. *et al.*, 1978; reviewed in Fain, G. L. *et al.*, 1996). It now appears that a large part of the decrease in sensitivity caused by bleaching actually comes from a finite, albeit weak, activity of opsin to activate the transduction process. This activity of free opsin has been demonstrated both in vitro (Okada, D. *et al.*, 1989; Surya, A. *et al.*, 1995) and in intact photoreceptors (Cornwall, M. C. and Fain, G. L., 1994; Fain, G. L. *et al.*, 2001). On a per-molecule basis, opsin has a very low ability to activate transduction, equivalent to 10^{-5}–10^{-7} that of Meta II (Cornwall, M. C. and Fain, G. L., 1994; Cornwall, M. C. *et al.*, 1995). However, in aggregate, the overall activity can still be substantial, especially if the percentage of bleached (bare) opsin is significant (say, 10% or more). This constitutive activity acts like steady background light to produce adaptation of the cell. The resulting desensitization is persistent in isolated photoreceptors, which have little 11-*cis*-retinal in them, and can only be reversed by the application of exogenous chromophore. The use of exogenous chromophore has also allowed the investigation of how, in the course of pigment regeneration, the initial noncovalent binding of

11-*cis*-retinal to opsin may affect the function of rods and cones. Interestingly, it is found that the initial bindings, noncovalently, of chromophore to rod and cone opsins have opposite effects (Kefalov, V. *et al.*, 2001). In rods, the constitutive activity of opsin is roughly doubled when chromophore binds noncovalently, whereas, in cones, noncovalent binding of chromophore already quenches free cone opsin activity completely (Kefalov, V. *et al.*, 2001). This property allows cones to recover from bleaching adaptation even faster than the actual regeneration of their pigment. In contrast, rod recovery from a bleach is delayed by the transient activation of opsin by noncovalently linked retinal.

The molecular mechanisms of some visual disorders can also be linked to the constitutive activity of mutant opsin similar in effect to bleaching adaptation. This idea, originally proposed by Fain G. L. and Lisman J. E. (1993), was recently confirmed by expressing in *Xenopus* rods mutant opsins with such a property that is linked to congenital night blindness (Jin, S. *et al.*, 2003).

Finally, early immunocytochemistry has suggested that $G_{T\alpha}$ can translocate from the outer segment to the inner segment of rods under light-adapted conditions (Brann, M. R. and Cohen, L. V., 1987). This phenomenon has been verified in recent years (Sokolov, M. *et al.*, 2002). Exposure to bright light induces translocation, of not only rod $G_{T\alpha}$ but also $GT_{\beta\gamma}$, out of the rod outer segment. Besides transducin, arrestin also translocates, but in the opposite direction, namely, to the outer segment from the rest of the cell. The idea has been proposed (Sokolov, M. *et al.*, 2002) that this en-mess translocation of transduction proteins serves the purpose of shutting down transduction – kind of an extreme form of light adaptation. However, the translocation can also be thought of as a protective mechanism against some forms of photodamage. The mechanisms by which the translocation occurs are still not understood. Two alternative proposals include passive diffusion driven by concentration gradients along the cell or active transport involving molecular motors (reviewed in Calvert, P. D. *et al.*, 2006). An interesting feature of transducin translocation is that there appears to be a steep threshold of light intensity below which transducin movement does not occur but above which massive translocation of transducin is observed (Sokolov, M. *et al.*, 2002). One possible explanation is that this threshold corresponds to the point where the ability of the cell to rapidly inactivate transducin becomes exhausted (Kerov, V. *et al.*, 2005).

1.10.13 Dark Adaptation

The recovery of sensitivity driven by pigment regeneration following bleaching is called dark adaptation. In order for dark adaptation to occur, the photoactivated pigment has to decay and the resulting free opsin has to regenerate with a fresh molecule of 11-*cis*-retinal supplied by the pigment epithelium. The so-called retinoid cycle involved in this process is complex, with some details only recently worked out. Because a large part of this process takes place in the pigment epithelium, dark adaptation is somewhat beyond the scope of this chapter. Recent reviews can be found elsewhere (Saari, J. C. 2000; Lamb, T. D. and Pugh, E. N., 2004).

1.10.14 Differences between Rods and Cones

As mentioned above, cones have a much lower sensitivity to light and faster response kinetics than rods, and they also adapt to light much more effectively. The mechanisms underlying these rod–cone differences in the context of a common phototransduction process are still an area of active research. It might be pointed out here that most, though not all, of the proteins involved in transduction have distinct isoforms in rods and cones, so some quantitative differences in the process between them are not surprising.

Considering that the activation of the visual pigment by light constitutes the first step of phototransduction, it is naturally the first place for scrutiny. One possible mechanism for the lower sensitivity and faster response kinetics of cones would be the well-known, significantly faster decay of the active Meta-II state of cone pigments. However, a direct comparison of the signaling properties of rod and cone pigments side by side in the same photoreceptor from transgenic animals has demonstrated that this is not the case (Kefalov, V. *et al.*, 2003). Thus, when expressed in rods, a cone pigment produces rod-like responses. By the same token, rhodopsin expressed in cones produces cone-like responses. The implication of this observation is that the decay of Meta II is not rate-limiting for the inactivation of pigment in intact cells, at least in dark-adapted conditions. Instead, the pigment is rapidly inactivated by rhodopsin kinase and arrestin. It is still possible, especially in cones, that the ability of the cell to inactivate the pigment will saturate under intense light,

rendering Meta-II decay dominant for the shutoff of the response. Because cone Meta II decays within several seconds (Wald, G. *et al.*, 1955; Okada, T. *et al.*, 1994), this will still allow cones to recover quickly from bright light. In rods, on the other hand, Meta II decays much more slowly and exists in equilibrium with the physiologically inactive Meta-III state (Heck, M. *et al.*, 2003), which has a lifetime of minutes and therefore rate-limits the overall recovery of rods from a bright bleaching light (Kolesnikov, A. V. *et al.*, 2003). Thus, while the visual pigments appear to play little role in the difference in light response properties between rods and cones in darkness or low light, this may not be the case in very bright light. In addition, cone pigments regenerate significantly more rapidly than rod pigments (Wald, G. *et al.*, 1955). Finally, as discussed in Section 1.10.8, the higher rate of thermal activation of red cone pigment compared to rhodopsin, as well as their dissociability, contributes to the lower sensitivity of red cones.

The visual pigments in both rods and cones are inactivated by phosphorylation by pigment kinase, or GRK, and the subsequent binding of arrestin. GRK exists as the rod-dominant GRK1 and the cone-dominant or cone-exclusive GRK7 (Ohguro, H. *et al.*, 1995; Tachibanaki, S. *et al.*, 2001; Weiss, E. R. *et al.*, 2001). The specific activity of GRK7 is over 10 times higher than that of GRK1 (Tachibanaki, S. *et al.*, 2005; Tachibanaki, S. *et al.*, 2007), implying a potentially faster cone pigment inactivation. In addition, in fish, the expression level of pigment kinase is tenfold higher in cones than in rods (Tachibanaki, S. *et al.*, 2005). The mouse represents an interesting and unusual case in that its rods and cones both express only GRK1 (Weiss, E. R. *et al.*, 2001). This simplicity has allowed the use of GRK1$^{-/-}$ mice, originally generated to investigate the role of phosphorylation in the shutoff of rod pigment (Chen, C.-K. *et al.*, 1999), to demonstrate that phosphorylation is also required for the proper inactivation of cone pigment (Lyubarsky, A. L. *et al.*, 2000). The same is true for GRK7 (Rinner, O. *et al.*, 2005). Rod arrestin is also shared between mouse rods and cones (Zhu, X. *et al.*, 2005). Interestingly however, the deletion of rod arrestin produces a dramatic delay in the shutoff of the rod response (Xu, J. *et al.*, 1997) but has no effect on the cone response (Lyubarsky, A. L. *et al.*, 2000). One possible explanation is that cone pigment is inactivated by a different, cone-specific arrestin identified recently (Zhu, X. *et al.*, 2002).

It is interesting that the RGS9 protein in the GAP complex involved in the deactivation of transducin is also present in much higher concentration in cones than in rods (Cowan, C. W. *et al.*, 1998; Zhang, X. *et al.*, 2003).

There are two isoforms of GC, GC1 and GC2, and two isoforms of GCAPs, GCAP1 and GCAP2 (each GCAP acts on both GCs). These proteins are present in both mouse rods and cones, although, more generally, the relative distributions of these proteins in rods versus cones, as well as the efficiencies of regulation of the cyclases by the GCAPs, appear to vary across species (reviewed by Gorczyca, W. A. and Sokal, I., 2002). The functional significance of the presence of two distinct isoforms of GCs and GCAPs in rod and cone photoreceptors is not presently understood, because their overall properties are not greatly different.

As discussed in Section 1.10.10, phototransduction in both rods and cones is subject to modulation by Ca^{2+}. During light, Ca^{2+} is extruded more rapidly from the cone outer segment than from the rod outer segment, at least partly because the much larger surface-to-volume ratio of the cone outer segment (Nakatani, K. and Yau, K.-W., 1989). The range of Ca^{2+} concentration change between darkness and light appears larger in cones than in rods (Sampath, A. P. *et al.*, 1999), possibly because of the higher fraction of dark current carried by Ca^{2+} (see Section 1.10.9) and the higher efficiency of the cone $Na^{+}/Ca^{2+},K^{+}$ exchanger NCKX2 compared to the rod exchanger NCKX1 (Korenbrot, J. I., 1995; Prinsen, C. F. *et al.*, 2000; Sheng, J. Z. *et al.*, 2000). Incidentally, the much larger surface area of the cone outer segment also speeds the release of all-*trans*-retinol from cones compared to rods following bleaching (Ala-Laurila, P. *et al.*, 2006).

1.10.15 Diseases

Rods and cones can be severely compromised by a variety of disease conditions, genetic or otherwise, that lead to their dysfunction or irreversible degeneration, causing a partial or complete loss of vision. In the past decade or two, tremendous advances have taken place in the understanding of many of these diseases, thanks to the revelations of the cellular and molecular details of rod and cone phototransductions. Because of the intimate relationship between the retinal pigment epithelium and the photoreceptors, the degeneration of the photoreceptors will also occur when the pigment epithelium malfunctions. Table 1 provides a fairly comprehensive list of the human diseases caused

Table 1 Photoreceptor's dysfunction resulting from gene mutations

Disease	*Symptom*	*Gene location*	*Protein*	*Reference*
Recessive retinitis pigmentosa	Retinal degeneration	3q22.1	Rhodopsin	Dryja, T. P. *et al.* (1990); Berson, E. L. (1993); Hartong, D. T. *et al.* (2006)
		4p16.3	Rod PDEβ (PDE6B)	Bowes, C. *et al.* (1990)
		4p12	CNGA1	Dryja, T. P. *et al.* (1995); Griffin, C. A. *et al.* (1993)
		16q13	CNGB1	Ardell, M. D. *et al.* (2000); Bareil, C. *et al.* (2001)
		5q33.1	Rod PDEα (PDE6A)	Dryja, T. P. *et al.* (1999); Pittler, S. J. *et al.* (1990)
		10q23.1	RPE-retinal G protein-coupled receptor (RGR)	Morimura, H. *et al.* (1999)
		4q32.1	Lecithin retinol acyltransferase (LRAT)	Ruiz, A. *et al.* (2001)
Dominant retinitis pigmentosa	Retinal degeneration	6p21.1	GCAP2	Sato, M. *et al.* (2005); Payne, A. M. *et al.* (1999)
Nougaret	Severe reduction in rod sensitivity, with mild reduction in cone sensitivity	3p21.31	Rod Tα (GNAT1)	Dryja, T. P. *et al.* (1996)
Oguchi	A stationary type of night blindness characterized by slow dark adaptation, the absence of visual loss	2q37.1	Rod arrestin	Fuchs, S. *et al.* (1995); Maw, M. A. *et al.* (1995)
		13q34	Rhodopsin kinase (GRK1)	Yamamoto, S. *et al.* (1997)
Dominant cone dystrophy	Progressive degeneration of cone photoreceptors, loss of visual acuity and color vision, and photophobia	6p21.1	GCAP1	Sokal, I. *et al.* (1998); Payne, A. M. *et al.* (1998)
Leber congenital amaurosis	Retinal degeneration	1p31.2	Retinal pigment epithelium-specific 65-kDa protein (RPE65)	Perrault, I. *et al.* (1999); Gu, S. *et al.* (1997); Marlhens, F. *et al.* (1997)
		17p13.1	GC1	Perrault, I. *et al.* (1996); Camuzat, A. *et al.* (1995)
Recessive achromatopsia	Color blindness	1p13.3	Cone Tα (GNAT2)	Aligianis, I. A. *et al.* (2002); Kohl, S. *et al.* (2002)
		8q21.3	CNGB3	Winick, J. D. *et al.* (1999); Milunsky, A. *et al.* (1999)
		2q11.2	CNGA3	Arbour, N. C. *et al.* (1997); Kohl, S. *et al.* (1998); Wissinger, B. *et al.* (1998)
Bradyopsia	Reduced ability to see moving objects with low contrast	17q24.1	RGS9	Nishiguchi, K. M. *et al.* (2004)
		19q13.12	R9AP	Nishiguchi, K. M. *et al.* (2004)
Recessive Stargardt disease	Age-related macular degeneration	1p22.1	ATP-binding cassette transporter (ABCR)	Allikmets, R. *et al.* (1997)
Fundus albipunctatus	Stationary night blindness	12q13.2	(11-*cis*-retinol dehydrogenase) RDH1 and 5	Cideciyan, A. V. *et al.* (2000); Nakamura, M. *et al.* (2000); Simon, A. *et al.* (1996); Yamamoto, H. *et al.* (1999)
Best's disease	Degeneration of the retinal fovea	11q13	Bestrophin	Marquardt, A. *et al.* (1998); Petrukhin, K. *et al.* (1998)

Refer to RetNet (see 'Relevant website') for a more complete database of retinal disease.

by mutations in known proteins in rods, cones, or the retinal pigment epithelium, along with their symptoms (for a complete list, see RetNet ('Relevant website' section)). The last one on the list, Best's disease, is caused by a protein named bestrophin, which recently has been found to be a hitherto unknown Ca^{2+}-activated chloride channel presumably involved in the transport function of the retinal pigment epithelium (Sun, S. *et al.*, 2002; Tsunenari, T. *et al.*, 2003; 2006). Because the fovea is so critical for everyday vision, any disease affecting this retinal region is particularly incapacitating to the patient.

1.10.16 Parietal-Eye Photoreceptor in Lizards and a Possible Evolutionary Linkage to Rods and Cones

The parietal (third) eye is quite unique to lizards (there is an analogous structure in amphibians called the frontal organ). It is situated on the forehead, in between the two regular (lateral) eyes. The exact function of this eye is still not entirely clear. The best suggestion so far is that it informs the animal about the passage of time in the course of the day by registering changes in the wavelength spectrum of the ambient light as the day progresses (Solessio, E. and Engbretson, G. A., 1993).

It resembles the two lateral eyes by having a cornea, a lens, and a retina (Eakin, R. M., 1973). The retina, however, has only photoreceptors, ganglion cells, and glial cells (i.e., no bipolar, horizontal, and amacrine cells). It is also opposite in orientation to the lateral-eye retina in that the photoreceptors face the front of the eye and are therefore the first neurons in the retina to encounter light. The photoreceptors have a well-formed outer segment, with orderly stacked disks. Electron microscopy indicates that the disks, like those in cones, are continuous with the plasma membrane (Eakin, R. M., 1973).

One very unusual feature of the parietal-eye photoreceptor is that each cell expresses two pigments (Su, C.-Y. *et al.*, 2006): the blue-sensitive pinopsin, first found in the light-sensitive chicken pineal gland (Okano, T. *et al.*, 1994; Max, M. *et al.*, 1995), and the green-sensitive parietopsin, an apparently ancient pigment not found in the lateral eyes. The coexistence of two pigments in a single cell fits with the physiology, which involves two antagonistic, cGMP-mediated phototransduction pathways in the same cell (Solessio, E. and Engbretson, G. A., 1993; Finn, J. T. *et al.*, 1997; Xiong, W.-H. *et al.*, 1998). One of these, best activated by blue light, is identical to that in rods and cones, consisting of cGMP-PDE stimulation, a decrease in cGMP concentration, closure of CNG channels, and a membrane hyperpolarization. The other, best activated by green light, consists of inhibition of the same PDE, an increase in cGMP concentration, opening of CNG channels, and a membrane depolarization. Thus, it appears that pinopsin activates the hyperpolarizing pathway and parietopsin the depolarizing pathway. Interestingly, transducin is not present in these cells. Instead, gustducin appears to take its role, coupling to pinopsin (Su, C.-Y. *et al.*, 2006). Although gustducin is not found in any other photoreceptor, it is nonetheless a close relative of transducin, with a similar protein sequence and function (McLaughlin, S. K. *et al.*, 1992; Hoon, M. A. *et al.*, 1995; He, W. *et al.*, 2002). G_o, on the other hand, appears to couple to parietopsin. G_o is more different from transducin and gustducin, although still belonging to the same subfamily of G proteins.

In vertebrates, the involvement of G_o in phototransduction is unique to the parietal-eye photoreceptor. However, in invertebrates, there is precedent for its involvement in vision, notably in the scallop hyperpolarizing photoreceptor, which is also of the ciliary type (i.e., with the photosensitive structure derived from a modified cilium) as rods, cones, pineal photoreceptors, and parietal photoreceptors. In this scallop photoreceptor, G_o is coupled to SCOP2, an apparently ancient pigment, to activate a cGMP-signaling pathway analogous, though not identical, to that in rods and cones (Kojima, D. *et al.*, 1997; Gomez, M. P. and Nasi, E., 2000). Thus, all evidence suggests that a G_o-mediated phototransduction pathway is ancient among ciliary photoreceptors. As such, the parietal-eye photoreceptor appears to be a living predecessor of rods and cones – a missing link between rods/cones and primitive ciliary photoreceptors. The notion is that a G_o-mediated phototransduction pathway existed in ciliary photoreceptors long ago, before vertebrates evolved from invertebrates. This pathway was retained in early vertebrates. In the course of evolution, however, a chromatically antagonistic, gustducin/transducin-mediated phototransduction pathway was added to the cells with the G_o-mediated pathway for the purpose of analyzing spectral information. This chromatic antagonism is retained by the parietal-eye photoreceptor to the present day. In parallel during evolution, the lateral eyes made their appearance over time but retained only the more recent gustducin/transducin-mediated pathway,

delegating the color opponency instead to downstream neurons – a good strategy because complex processing of color information is best provided by elaborate synaptic circuitry. As such, the chromatic opponency within a single parietal-eye photoreceptor represents a very primitive, simple form of color vision compared to, say, what goes on in the lateral-eye retina.

Incidentally, the parietal eye, like the two lateral eyes, develops as a protrusion of the diencephalon of the brain during embryogenesis (Eakin, R. M., 1973).

1.11.1 Introduction

Mammalian retinas are generally dominated by rods that normally constitute 90–97% of all the photoreceptors. Noticeable exceptions are few, purely diurnal animals (such as ground squirrels and three shrews, whose retinas are considered as cone-only), and highly specialized retinal areas, which include the area centralis of the cat, the visual streak of the rabbit, and the primate fovea. In these regions, cones represent the vast majority, if not the entire population, of photoreceptors. Given the fact that specialized, cone-enriched zones cover up a limited fraction of the retinal surface, even mammals which have evolved such dedicated areas are, in the end, rod dominated.

In most cold-blooded vertebrates, rods, and cones usually converge unto common second-order neurons; mammals, instead, exhibit multiple types of bipolar cells collecting information from cones, and one, single type of bipolar cell, entirely dedicated to gather signals from rods. The typical mammalian rod bipolar cell (Figure 1) is one of the best-characterized neurons of the central nervous system (CNS). It has been illustrated first by Santiago Ramón y Cajal, in his pioneering studies of Golgi-impregnated neurons and has a typical morphology, with a bushy, chandelier-like dendritic arborization, an ovoidal cell body, usually positioned at the outer aspect of the inner nuclear layer, a thin axon, and a stout axonal arborization, composed of large varicosities, which reach the deepest part of the inner plexiform layer (IPL), at the limit to ganglion cell bodies. In his handmade drawings of Golgi-stained retinas, Cajal represented the axonal endings of rod bipolar cells in close contact with the cell bodies of ganglion cells, postulating a direct pipeline conveying rod information to the final neurons projecting out of the retina. His discovery of two separate sets of bipolar cells, respectively, dedicated to cones and to rods, dictated enthusiastic words to his memories, reported in his biography *Recollections of My Life*:

> Observe how one variety of bipolar makes a contact through its ascending dendritic tuft with a group of terminal bulbs of the rods; while the axonic or deep process of the same cell, forming a warty foot, connects below with the body of a certain giant ganglionic neuron (Cajal, Santiago Ramón y, 1989).

Modern electron microscopy has discovered that the warty foot does not establish connections (synapses, totally unknown at Cajal's time) with ganglion cells. Indeed, synaptic contacts with cell bodies are rare in the retina, most of the connections being segregated in the two plexiform layers. But rod bipolar cells do not make connections with ganglion cell dendrites either: they utilize a chain of neurons ultimately leading to the confluence of rod- and cone-generated signals into common cohorts of ganglion cells.

This concept was totally illogical for Cajal's straightforward way of thinking (from which the concept of inhibition was entirely absent, for historical reasons): to him, separate rod and cone bipolar (CB) cells were "demanded by theory and guessed by rationale"; he could see no reason "why the ingenious expedient according to which nature has organized two classes of specific photoreceptor cells would be completely frustrated. . .." by mixing up rod and cone signals into a sole bipolar or, at a later stage of neural processing, into a common ganglion cell. We shall see later that the functional benefits of the ingenious expedient are indeed preserved, albeit the mixture of rod and cone pathways.

A close look at the very first synapse established in the outer plexiform layer (OPL) between rods and rod bipolar cells reveals that the terminal ending of

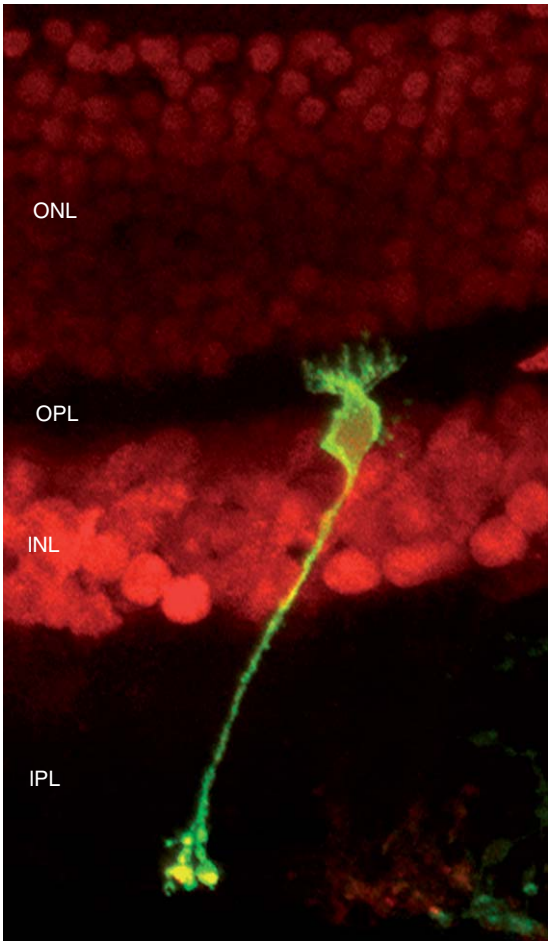

Figure 1 Rod bipolar cell of the mouse retina, individually labeled by a green fluorescent dye, in a vertical sections, in which cell nuclei have been stained with a red fluorescent molecule. The morphology of rod bipolar cells is highly conserved across various mammalian species. The body is ovoidal, the dendritic tree is chandelier shaped, and the axonal arbor is composed of several, large varicosities, which reach the deepest part of the IPL, close to the cell bodies of ganglion cells. For all the figures: GCL, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; ONL, outer nuclear layer; OPL, outer plexiform layer.

each dendrite of a rod bipolar cell penetrates deeply in the spherule, the synaptic terminal of a rod (Figure 2). The presynaptic membrane is marked by specialization named ribbons (R), a complex laminar sheet regulating the release of vesicles that fill the spherule cytoplasm. Opposed to each ribbon, a triad of processes is found: the two lateral elements originate from the axonal arborizations of horizontal cells (H in Figure 2); the central element of the triad is the dendrite of one rod bipolar cell (B). As a rule, a spherule makes contact with only one (or two) rod

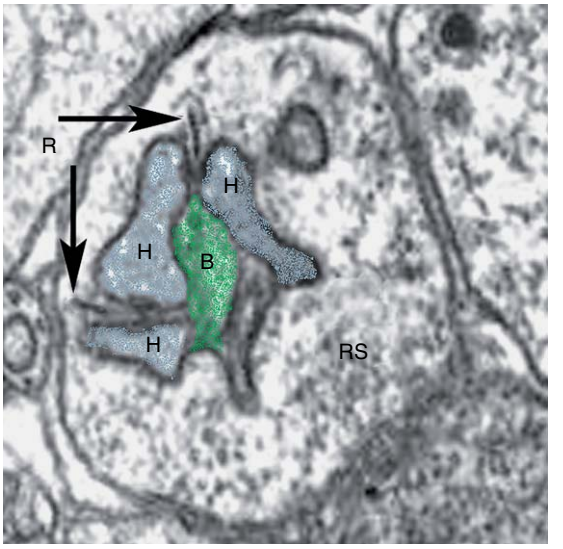

Figure 2 Electron micrograph of the synaptic terminal of a rod photoreceptor, termed spherule (RS). The cytoplasm is filled with synaptic vesicles; presynaptic sites are marked by dense ribbons (R). Postsynaptic processes are arranged in triads, in which lateral elements belong to horizontal cells (H, light blue processes) and the central element is the dendrite of a rod bipolar cell (B, green).

bipolar dendrites. This contact, named invaginated, is the only kind of synapse established by rod spherules. Unlike cone pedicles, therefore, in general rod spherules are not engaged in basal contacts.

At the postsynaptic site of the invagination, rod bipolar dendrites carry a retinal-specific type of metabotropic glutamate receptor, named mGluR6 (Ueda, Y. *et al.*, 1997). A high-resolution confocal image (Figure 3) shows terminal dendritic branches of rod bipolar cells (labeled green with antibodies against protein kinase C), decorated with clusters of red puncta, representing aggregates of mGluR6, exactly located at their tips. Each spherule contains one punctum, rarely two of them.

Figure 4 shows the profiles of rod spherules, labeled green with antibodies against the synaptic protein PSD95, encircling individual rod bipolar dendritic tips in the OPL. Via mGluR6, a graded hyperpolarization (representing the response triggered by light in rods) is transformed into a graded depolarization of postsynaptic rod bipolar cells. For that reason, invaginating synapses are called sign-inverting. Rod bipolars are depolarized by light stimuli that fall onto the center of their circular receptive fields: hence, they belong to the functional category of ON center neurons. As for ON center CB cells, rod bipolar cells are hyperpolarized by light

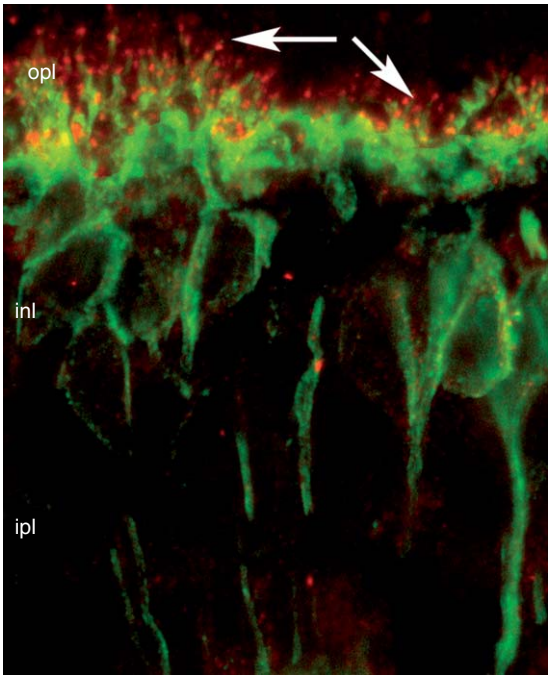

Figure 3 Confocal image of rod bipolar cells, labeled green by antibodies against protein kinase C, showing clusters of mGluR6 receptors on their dendritic tips (arrows, red labeling). This variety of glutamatergic receptor is almost unique to the retina.

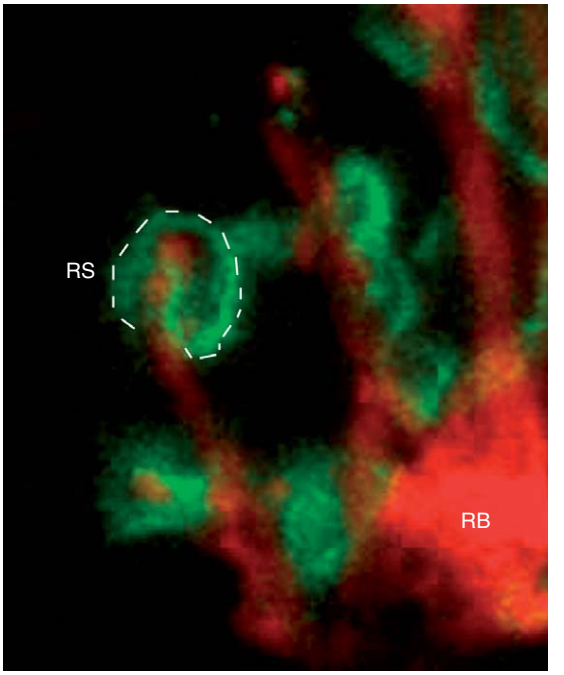

Figure 4 High-power confocal micrograph of rod spherules (RS), labeled green by antibodies against the synaptic protein PSD95. The profile of one spherule has been marked by a dashed line. Individual dendrites of rod bipolar (RB) cells (red staining) penetrate the spherules deeply, to receive ribbon synapses.

falling onto the annular area forming the periphery of their receptive fields. Therefore, they exhibit a typical OFF response at peripheral stimulation (Dacheux, R. F. and Raviola, E., 1986).

The number of rods converging upon a single rod bipolar cell varies greatly with the mammalian species and, within a species, with retinal eccentricity. In the periphery of a rabbit retina, where rods make up 97% of all photoreceptors, and dendritic arborizations of neurons are large, up to 80 rods converge upon a single bipolar cell. Near to the visual streak, dendritic trees become smaller, and the convergence is lower (about 60 rods for each bipolar). Regardless to retinal eccentricity, convergence in the rod pathway is usually higher than in the cone pathway. This contributes to the higher light sensitivity of the rod system, partially achieved through summation of inputs at postsynaptic level. Thus, the enormous amplification in individual rod photoreceptors (Baylor, D. A., *et al.*, 1979) and convergence within the rod bipolar pathway (Sterling, P. *et al.*, 1988), confer retinal ganglion cells, the retinal output neurons, a huge sensitivity: a cat ganglion cell can produce several extra spikes when one of the thousands of rods within its receptive field absorbs a single photon (Field, G. D. *et al.*, 2005).

All together, a rod spherule is less varied (in number of synaptic partners, as well as in types of synaptic contacts established), than a cone pedicle. Hence, if one had to limit the analysis of the rod pathway at the first synaptic station of the retina, the conclusion would be that there is neither scotopic contribution to the OFF channel nor parallel processing of signals generated in rods. This is not the case.

Both the OFF channel and the computation arising from parallel processing are opened to the rod pathway by means of an interposed, peculiar neuron, a small-field amacrine cell, named AII. AII amacrines were first described by Kolb H. (1979) in the cat retina. They are narrow-field neurons, with a typical, bistratified morphology (Figure 5). The outermost arborization is composed by round endings, called lobular appendages; the inner part is represented by a tangle of thin, elongated dendrites, with laterally oriented terminal tips. They are called tufted processes and occupy the innermost part of the IPL. Electron microscopy of serial sections has clearly demonstrated that AII amacrine cells are the main

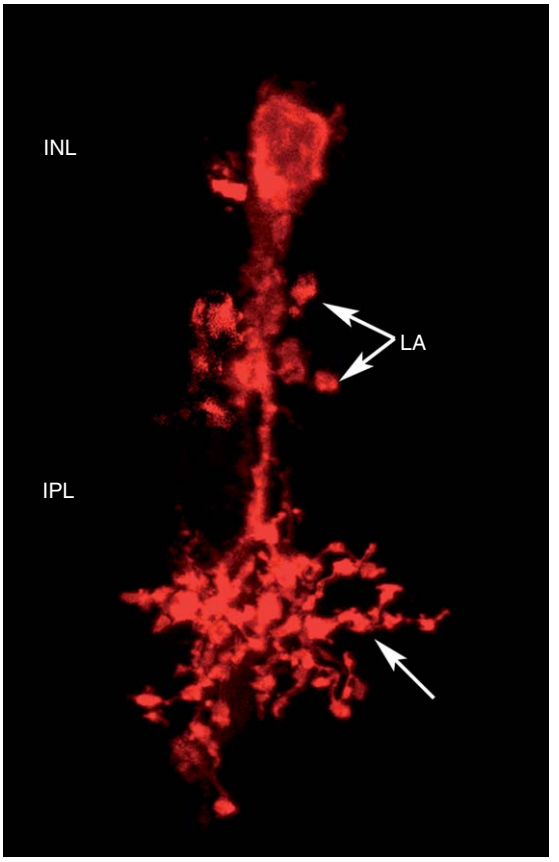

Figure 5 Single AII amacrine cell of the mouse retina. The typical bistratified morphology is clearly evident. Tufted processes receive synaptic inputs from rod bipolar cells in the innermost part of the inner plexiform layer (arrow), while lobular appendages (LA) establish output synapses in the outer half of the IPL.

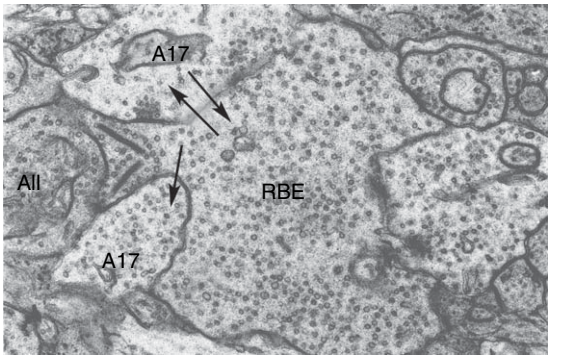

Figure 6 Electron micrograph of a rod bipolar axonal ending (RBE), with its typical synaptic arrangement. Two ribbon synapses are visible, with one dark dendrite, belonging to an AII amacrine cell, and two pale varicosities, filled with vesicles, belonging to A17 amacrine cells. One of them returns a reciprocal synapse onto the rod bipolar ending itself (arrow).

postsynaptic target of rod bipolar cells (Strettoi, E. *et al.*, 1992). The latter establish ribbon synapses (similar to those already found at photoreceptor synaptic terminals) in the deepest layer of the IPL with the tufted dendrites of AII amacrine cells.

A typical synaptic arrangement is depicted in Figure 6, in which a rod bipolar axonal ending establishes a dyad with two processes of different cytology. The dark, electron-dense dendrite, with few vesicles and a gray matrix, belongs to an AII amacrine cell. The other ending, filled with pale synaptic vesicles, belong to a wide-field amacrine, also known as A17. This is an indoleamine-accumulating amacrine and a gamma-aminobutyric acid (GABA)-releasing neuron. As for the AII, the major synaptic input to this cell is derived from rod bipolar cells; unlike AII amacrines, however, A17 cells are not projection neurons. Their function is exquisitely local, as they return feedback, inhibitory synapses onto the axonal endings of the rod bipolar itself (Sandell, J. H. *et al.*, 1989). Both AII and A17 amacrines respond to light with a graded depolarization, similar to that recorded in a rod bipolar cell. However, because of a feedback inhibitory loop created by A17 cells upon rod bipolar endings, AII responses become more transient that their rod bipolar input responses (Raviola, E. and Dacheux, R. F., 1987). Local feedback inhibition is a recurrent strategy of the CNS wiring diagram by which transient components of neuronal responses are enhanced.

If, then, the rod-generated signal cannot proceed further in the retinal pathway through A17 amacrines, it follows that the sole cell responsible for the progression of scotopic responses to the subsequent retinal synaptic station is represented by the AII amacrine. In fact, because of the peculiar, bistratified morphology of this interneuron, a dichotomy is generated in the rod pathway: each AII amacrine cell establishes sign-conserving gap junctions with the axonal endings of CB cells that ramify in the deepest layer of the IPL (or ON CBs; Figure 7); the lobular appendages of the same cell form sign-inverting, glycinergic synapses with OFF CBs, whose axons ramify in the outer half of the IPL.

Electrophysiology has demonstrated strong electrical coupling with symmetrical junction conductance between AII amacrine cells and various types of ON CB cells. However, signal transmission is more effective in the direction from AII amacrine cells to ON CB cells than in the other direction (Veruki, M. L. and Hartveit, E., 2002).

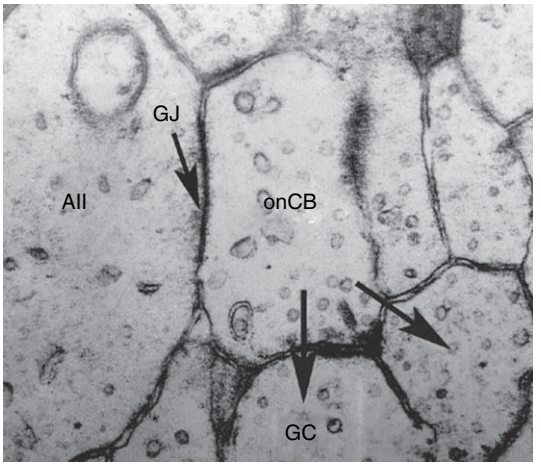

Figure 7 The primary dendrite of an AII amacrine cell establishes a large gap junction (GJ) with the axonal ending of a cone bipolar (CB) cell in the innermost part of the IPL (sublamina ON). In turn, the CB feeds a ribbon synapse to a ganglion cell (GC) dendrite. By this peculiar arrangement, the light response of an AII amacrine upon illumination (a graded depolarization) is transferred to the ON pathway of the retina, retaining its sign.

In the outer sublamina of the IPL, OFF CB cells receive a strong glycinergic input from the lobular appendages of AII amacrine cells; this input is preferentially based on the fast alpha1beta-containing channels (Ivanova, E. *et al.*, 2006). As a result, the depolarizing response generated by the fall of photons upon the central receptive field of a rod bipolar cell is first transformed into a more transient depolarizing response of AII amacrine cells, then split into the ON and the OFF channels, and finally fed into the cone pathway with great efficiency (Figure 8).

It is interesting to note that only few, direct synapses, are formed between AII amacrine cells and dendrites of ganglion cells. If some of these neurons had to collect a large number of AII amacrine inputs, they could be considered as mainly rod-dominated. However, physiology suggests that even in strongly rod-dominated, nocturnal animals, ganglion cells that are mostly rod-driven are encountered only rarely. Through AII amacrines, the largest part of the scotopic signal is infused directly into the cone pathway, in what is known as a piggyback arrangement. Further on, separate rod and cone pathways converge onto common ganglion cells. To our present knowledge, there are no privileged types of CB cells, either in the ON or in the OFF pathways, which establish connections with AII amacrine cells. Presumably, most of the ON CBs are engaged in gap junctions with the tufted processes of AII amacrines;

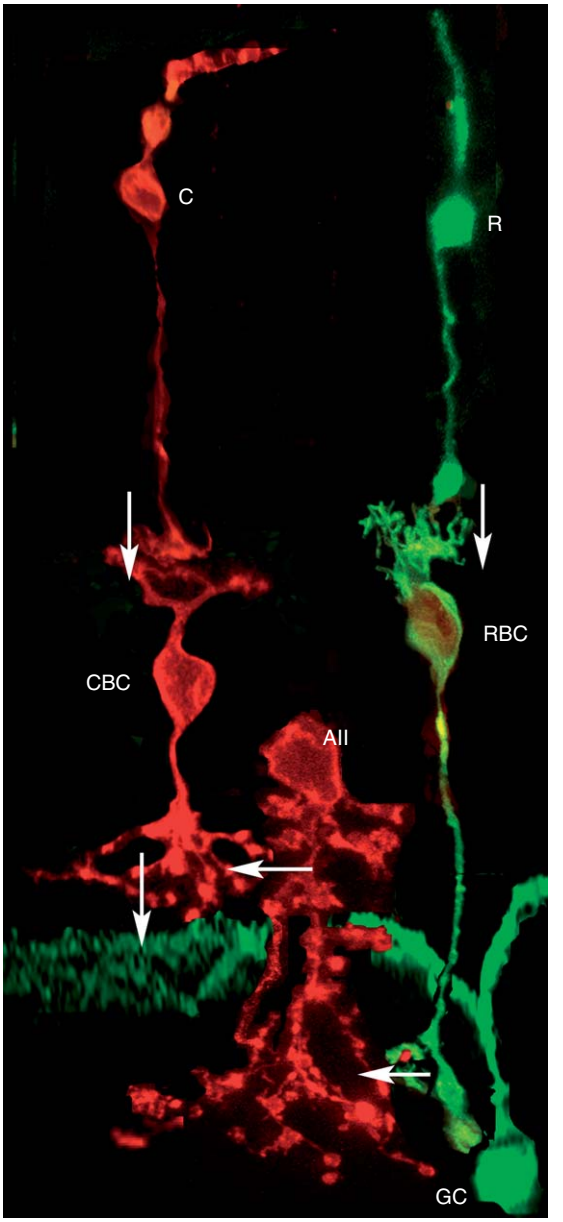

Figure 8 The rod pathway. Montage of neurons of the rod pathway stained individually by delivery of lipophilic, fluorescent dies, in the mouse retina. Rods (R) and cones (C) converge upon separate sets of bipolar cells. Because of rod bipolar (RB) cells make connections to AII amacrine cells and these, in turn, feed the information to cone bipolar (CB) cells, the rod pathway is a five-neuron chain. Direct connections to ganglion cells (GCs) are mostly established by means of chemical synapses between CB axonal endings and GC dendrites.

similarly, it is likely that most of the CB cells with axonal arbors in sublamina OFF are postsynaptic to AII lobular appendages. Thus, the role of information transfer of the scotopic signal from AII amacrines to

ganglion cells is almost entirely committed to the axonal arbors of ON and OFF CB cells. This transfer is operated through further sets of synaptic connections, represented by sign-conserving ribbon synapses, established between ON and OFF CB axonal endings and corresponding sets of ganglion cell dendrites, in the ON and OFF laminae of the IPL. These synapses use glutamate as a neurotransmitter.

A part of the rod pathway is summarized in Figure 9. This is a montage of mouse neurons, individually labeled with lipophilic, fluorescent dies delivered to retinal slices by a gun and propelled by helium gas. The images obtained are reminiscent of those achieved by means of classical Golgi impregnation.

There are several checkpoints in the piggyback arrangement described so far: first of all, CB cells return feedback synapses onto the lobular appendages of AII amacrine cells. This implies transfer of information from the cone to the rod system. Moreover, each AII amacrine receives profuse innervation from dopaminergic amacrine cells. These are rare, wide-field neurons (less than 600 of them in the retina of a mouse, which contains globally some 600 000 amacrine cells), with arborizations located in the outermost portion of the IPL (the sublamina 1). Dopamine, released in the dark, is a powerful modulator of gap junction permeability, and an overall regulator of retinal sensitivity to light. Dopamine controls many components of the retinal circuitry; it alters the gap junctional conductance between horizontal and amacrine cells, increases the responses of ionotropic glutamate receptors on bipolar cells, and ultimately affects the center-surround balance of ganglion cells. In several cases, dopamine action is mediated nonsynaptically, via a paracrine release of the neurotransmitter (Witkovsky, P., 2004).

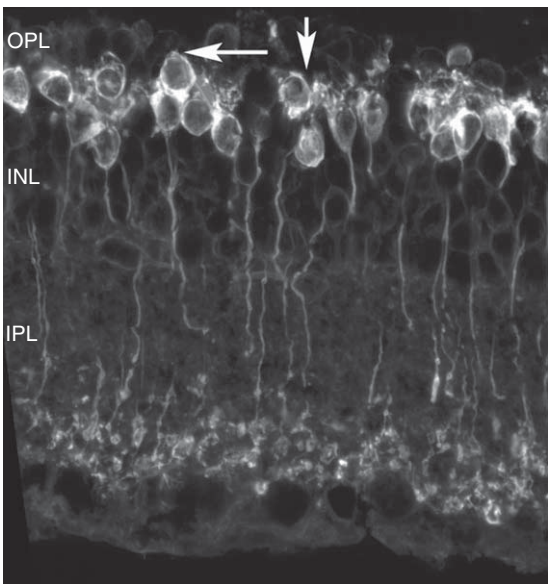

Figure 9 Vertical section of the retina of a mouse mutant in which photoreceptors have totally degenerated (rd10 mutant). In this and other mutations, rod bipolar cells retract their dendritic trees, which show an almost total secondary atrophy (arrows).

The AII amacrine is the nodal point where rod and cone, as well as ON and OFF pathways, intersect. Within scotopic levels of illumination, light stimuli hyperpolarize rods, eliciting a decrement in their glutamate release; this, in turn, depolarizes rod bipolar cells, causing the release of glutamate from their axonal endings onto the A17 amacrine cell and the AII amacrine cell. Glutamate excites the AII, causing at the same time: the release of glycine onto OFF CB cells, and thus the inhibition of OFF ganglion cells; the depolarization of ON CB cells via gap junctions, and thus the excitation of ON ganglion cells; the diffusion of the signal through the network of AIIs, also coupled through homologous gap junctions. In turn, AII responses are modified by inhibition from depolarized A17 amacrines through their feedback onto rod bipolar axonal endings. Thus, rod-generated signals produce inhibition of the OFF pathway and excitation of the ON pathway.

In bright light (photopic) conditions, AII amacrine cells receive inputs from both ON (through gap junctions) and OFF CBs (by means of conventional, chemical synapses). ON center responses are stronger and elicit glycine release from AII lobular appendages. In turn, these inhibit OFF CB cells. Moreover, because of the weaker coupling of gap junctions during bright light, the dissipation of cone signals through the AII network is limited, so that this can reach effectively ganglion cells. The net result is that the OFF channel is inhibited by the ON retinal channel and that high-acuity cone signals are preserved. In scotopic and photopic conditions, under the control of dopaminergic innervation, the AII amacrine cell operates as a switch from one input pathway to another, with high efficiency.

1.11.2 Additional Rod Pathways

Cone pedicles have thin, basal processes, named telodendria, that project horizontally to the OPL, forming small gap junctions with neighboring rod spherules and cone pedicles (Raviola, E. and Gilula, N. B., 1975). In

principle, such connections, that mix signals from photoreceptors of different sensitivity and different absorption spectra, appear to degrade visual perception, and particularly that of color. Physiology has shown in a long time that mammalian cones carry rod signals (Nelson, R., 1977), which appear as a slow hyperpolarization following the initial response to a brief flash of light. Although the utility of such an arrangement is still a matter of debate, through gap junctions with cones, rod signals can utilize the fast-tuned cone pathways to reach the IPL.

A novel family of connections has been identified recently in the outer retina of several mammalian species. Some OFF CB cells make symmetrical contacts with rod spherules and therefore collect direct input from rods (Hack, I. *et al.*, 1999; Tsukamoto, Y. *et al.*, 2001; Protti, D. A. *et al.*, 2005). Dendrites of such CBs appear to express ionotropic glutamate receptors at the site of apposition to rod spherules. Hence, besides the main pathway constituted by rod bipolars, AII amacrines, CBs, and ganglion cells, rod-generated signals can exit the retina through gap junctions between rods and cones as well as through this third pathway, using mixed cone–rod bipolar cells.

Although the alternative rod pathway was first discovered in the retina of rodents, anatomical evidence for direct connections between rods and OFF CB cells was later provided for the rabbit retina as well (Li, W. *et al.*, 2004). Electrophysiological recordings in the presence of drugs, capable of interfering with the scotopic transmission at various synaptic levels, demonstrated that around one-half of the ganglion cells in the rabbit retina receive off signals through a circuit that is independent of rod bipolar cells. In the mouse retina, however, a very low proportion of OFF signals carried in parallel to rod bipolar cells can be revealed, while no ganglion cells at all in the rat retina display off responses attributable to direct, flat contacts between rods and OFF CB cells as an alternative route (Protti, D. A. *et al.*, 2005). This suggest that the alternative rod pathway may be a common feature of the mammalian retina, but the relative importance and significance of this pathway differ between species. Noticeably, all the three rod pathways (both the classic and the two indirect ones) make use of CB axonal endings to gain access to ganglion cells.

1.11.3 How Could This Particular Synaptic Disposition Be Evolved?

A likely hypothesis is that the various rod pathways (and, particularly, the piggyback arrangement) have an evolutionary explanation: cone-mediated vision in bright light conditions evolved first, in parallel to color vision. This happened in ancestral vertebrates, with dim light vision appearing only after the evolution of the jawed vertebrates (Bowmaker, J. K., 1998). Hence, inner retinal circuitry was first shaped by cones: as each cone brings in a number of CB cells (ON, OFF, transient, sustained, etc.), one can postulate the hypothesis that the antique vertebrate retina was constituted by several types of CBs and cone-driven amacrine cells that shaped the responses of various types of ganglion cells.

When, later in evolution, rhodopsin appeared, as an effect of duplication of preexisting opsin genes, this pigment became segregated in a subtype of photoreceptor, the ancestor of a modern rod. The advantages of a dual retina were obvious: vertebrates could expand their life style to become partly nocturnal, colonizing additional habitats. To make the whole retinal network available to the newly evolved rods, it was not necessary to generate an additional inner retina. Useless duplication (with an undesirable increase in retinal thickness) was avoided introducing two novel interneurons: rod bipolar cells and AII amacrines. The first ensured retention of high sensitivity in the scotopic pathway by collecting information from a high number of rods. The second interneuron recruited the preexisting cone pathways, by establishing adequate connections with ON and OFF CB cells in the IPL. Through the evolution of this ingenious piggyback system, the whole neural network, previously reserved to cones, could be exploited by the newly evolved rods. Among other mechanisms, the switch in sensitivity of photopic versus scotopic pathways was ensured at inner retinal level by dopaminergic control of gap junction permeability.

This is somehow reflected in the fact that, contrary to the general belief, and as demonstrated by modern neuroanatomical techniques, CB cells largely outnumber rod bipolars, even in mammalians that are strongly rod dominated such as rodents. In these animals, cones are only 3% of all the photoreceptors (Jeon, C. J. *et al.*, 1998). Yet, CB cells are at least two times more numerous than rod bipolars. In a rabbit central retina, where cones are more abundant, CB cells outnumber rod bipolar cells by four to five times (Strettoi, E. and Masland, R. H., 1995). This is partly explained by the large converge of photoreceptors-to-bipolars characteristic of the rod system; however, part of it is accounted for the large variety of CB cells, acting in parallel and performing different types of computations (for instance, on temporal

properties) of the light-generated signals. Ultimately, the piggyback arrangement ensures the access of the scotopic signal to parallel processing, originally evolved in the cone system.

It is often underlined how AII amacrines are somewhat connotative of a mammalian retina; yet, cone-only retinas, or retinal areas from which rods are absent (such as the primate foveolar tip), lack AII amacrine cells completely. This also indicates that this cell evolved as a rod-system interneuron; in addition, a peculiarity of the AII is represented by the fact that this neuron belongs to the retinal vertical pathway more than to the horizontal, modulatory network, to which amacrine cells are traditionally assigned.

1.11.4 Inherited Photoreceptor Degeneration: How Photoreceptor Death Affects the Architecture of the Rod and Cone Pathways

A high number of mutations can occur in photoreceptors, with at least 100 of them affecting the rhodopsin gene alone (Mendes, H. F. *et al.*, 2005). The consequence is usually the progressive death of rods, followed by the secondary degeneration of cones, and subsequent blindness. These are the hallmarks of retinitis pigmentosa (RP), a family of inherited diseases characterized by progressive death of rods, initial loss of scotopic vision, secondary death of cones and, later, loss of all the effective sight. Many animal models of RP (Dalke, C. and Graw, J. 2005), and rodents in particular, are available to investigators to study this, otherwise rare, human disease, which affects 1 over 3500 individuals. These models have contributed invaluable tools to study the genetics as well as several biological aspects of this pathology, which is now well characterized in terms of symptoms and genetics.

Interestingly, very few investigators have been interested in understanding possible effects of photoreceptor degeneration upon other retinal cells, and particularly upon the neurons to which they are synaptically connected. This issue is however relevant for perspective therapies aimed at repairing the RP retina, and particularly for those approaches based on cellular transplantation (Lund, R. D. *et al.*, 2001) or implants of electronic devices (also known as silicon-retinal implants) (Loewenstein, J. I. *et al.*, 2004). Indeed, by examining the retina of various mouse mutants mimicking human RP, we detected secondary modifications of cells in the deeper retinal layers, and particularly in the neurons of the rod pathway described above (Marc, R. E. *et al.*, 2003). It appears that, concomitant to photoreceptor death, a stereotyped chain of events affects inner retinal cells, suggesting a close dependence of postsynaptic neurons from their afferent partners. The most striking feature is a dramatic regression of dendritic arbors in rod bipolar cells, associated to an abnormal localization and downregulation of the metabotropic glutamate receptor mGluR6.

Changes in horizontal cells are also quite striking. These neurons are connected to cones with their cell bodies and dendrites, and to rods by means of their axonal arborization. Both portions of the cells undergo a process of remodeling which follows photoreceptor death: ultimately, axonal endings loose their fine ramifications and grow enormously, covering the retina with a very loose mesh of processes. Later, the cell bodies become hypertrophic and loose the dendrites. After rod bipolar and horizontal cells, also CB cells start to show major anatomical changes; by the time that cone degeneration becomes complete, they retract their dendrites and show regressive changes similar to those described for rod bipolar cells. As reported above, CB cells are the most numerous interneurons of the mammalian retina. Their integrity is of clinical relevance, as they are a potential platform for therapeutic intervention.

Following abnormalities of their morphology, inner neurons retinas do eventually die out as a consequence of photoreceptor degeneration. Both rod bipolar and horizontal cells undergo a process of death that progresses slowly but continuously.

All together, these data point out clearly that the maintenance of a normal morphology, which include a dendritic tree and a normal complement of synaptic receptors, in second-order neurons, require the presence of viable photoreceptors. For this reason, RP cannot be considered as a pure photoreceptor disease: because it affects the very first neuronal type of a complex network of the CNS, RP should be considered a true central affection; thus, as any other neurological disorders, the whole network should be taken into account, rather than the affected cells only. This is a key concept when devising strategies aimed at restoring vision in RP: a timely intervention is required to precede widespread, adverse effects upon those neurons of the inner retina that represent the only network through which replaced photoreceptors or artificial implants can communicate with the visual part of the brain.

1.12.1 Introduction

It is well established that visual signals in the brain are processed in parallel, with contours, color, movement, stereopsis, and even more specific features such as facial expressions being processed in different brain areas (Casagrande, V. A. and Xu, X., 2004). The visual pathway from the eye to the brain is also organized into parallel streams, and fiber groups of the optic tract project to different subcortical areas such as the suprachiasmatic nucleus, the ventral and lateral geniculate complex, the pretectum, the superior colliculus, and the accessory optic nuclei. These brain areas have different roles in visual function and accordingly receive inputs from retinal ganglion cells (RGCs) which perfectly subserve such specific roles. For example, the suprachiasmatic nucleus, which regulates circadian rhythms, or the pretectum, which adjusts the pupil size, receive inputs from the recently discovered melanopsin-containing ganglion cells. They have intrinsic light responses in their dendrites and transmit a sustained light signal (Berson, D. M., 2003). Parallel routes can also be distinguished in the visual pathway that is commonly attributed to conscious vision, namely the projection from the eye through the lateral geniculate nucleus (LGN) to the visual cortex. Here, in primates, the parvocellular and magnocellular pathways are well established, and a third parallel tract is relayed in the intralaminar regions, the K-layers, of the geniculate (Hendry, S. H. and Reid, C., 2000).

Considerable processing and filtering of visual information occurs at the earliest stage of the mammalian visual system – the retina. In any mammalian retina there may well exist as many as 15 different ganglion cell types which cover the retina homogeneously with their dendritic fields. They represent 15 specific filters which encode in parallel different aspects of the image projected onto the retina. Ganglion cells receive specific inputs from bipolar and amacrine cells in the inner plexiform layer (IPL). The IPL is precisely stratified and the different ganglion cell types have their dendrites at specific levels within the IPL (Isayama, T. *et al.*, 2000; Sun, W. *et al.*, 2002; Dacey, D. M. *et al.*, 2003; Kong, J. H. *et al.*, 2005; Kim, T. J. and Jeon, C. J., 2006). The axons of bipolar cells, which transfer the light signals from the photoreceptors to the ganglion cells also terminate at distinct levels within the IPL (Ghosh, K. K. *et al.*, 2004). This suggests that the neurally encoded retinal image is different at different levels of the IPL, depending upon stratification of the various bipolar, amacrine, and ganglion cells (Roska, B. and Werblin, F., 2001). Bipolar cells provide the major excitatory drive for ganglion cells and their physiological signature, for instance OFF- or ON-light responses, is transferred onto ganglion cells. The physiological signature of bipolar cells in turn is defined by the glutamate receptors (GluRs) they express at their synaptic contacts with the cones. Parallel processing within the retina, therefore, begins already at the first synapse of the retina and here the molecular composition of GluRs represents the origin of the different channels (Wässle, H., 2004).

1.12.2 The Photoreceptor Synapse

1.12.2.1 The Presynaptic Complex

Cones respond to a light stimulus with a graded hyperpolarization and release their transmitter glutamate at a specialized synaptic terminal named cone pedicle. Transmitter release is high in darkness and is reduced by illumination of the cone. The cone pedicle is a giant synapse with multiple release sites and numerous postsynaptic partners (Figure 1). In the primate retina the cone pedicle increases from a diameter of approximately 4–5 µm close to the fovea to 8 µm diameter in peripheral retina. It contains between 20 and 50 presynaptic ribbons (Figures 1(c) and 1(e)), each of which is flanked by synaptic vesicles (Haverkamp, S. *et al.*, 2000; 2001). The synaptic terminal of rod photoreceptors, the rod spherule is smaller than the cone pedicle (~3 µm diameter) and contains one or two synaptic ribbons and release sites. The photoreceptor synaptic ribbon is a curved plate, ~30 nm thick, it extends ~200 nm into the cytoplasm and varies in length from 200 to 1000 nm. In rod spherules it is bent like a horseshoe (Figure 1(e)) and commonly cracks into two parts (Migdale, K. *et al.*, 2003). The ribbons are involved with the synaptic machinery of transmitter release and appear to represent a specialization of synapses, which have a sustained release of glutamate such as photoreceptors, bipolar cells, and auditory and vestibular hair cells (von Gersdorff, H., 2001; Heidelberger, R. *et al.*, 2005; Sterling, P. and Matthews, G., 2005). Proteins at the ribbon are just beginning to be identified and represent a specialization of the cytomatrix comparable and complementary to proteins present at the active zones of conventional synapses (tom Dieck, S. *et al.*, 2005; Deguchi-Tawarada, M. *et al.*, 2006). The proteins segregate into two compartments at the ribbon: a ribbon associated compartment including Piccolo, RIBEYE, CtBP1, RIM1, and the motor protein KIF3A, and an active zone compartment including RIM2, Munc 13-1, CAST1, and a calcium (Ca^{2+})-channel $\alpha 1$ subunit (Figure 1(b)). A direct interaction between the ribbon specific protein RIBEYE and bassoon seems to link the two compartments and is responsible for the integrity of the photoreceptor ribbon complex. In bassoon knockout mice the ribbons are no longer linked to the active zone and transmitter release is not possible (Dick, O. *et al.*, 2003). Fish deficient in RIBEYE lack an optokinetic response and have shorter synaptic ribbons in photoreceptors (Wan, L. *et al.*, 2005). The ribbons tether numerous synaptic vesicles (Usukura, J. and Yamada, E., 1987) and it has been suggested that they represent a conveyor belt transporting continuously synaptic vesicles toward the active zone (Gray, E. G. and Pease, H. L., 1971; Muresan, V. *et al.*, 1999). However, this is an oversimplification, because disruption of the actin cytoskeleton did not influence transmitter release (Heidelberger, R. *et al.*, 2002; Holt, M. *et al.*, 2004; Heidelberger, R. *et al.*, 2005). Ribbons, however, might serve as a platform along which vesicles can be primed for sustained release. Vesicles docked at the active zone probably represent the fast releasable pool. It has been estimated that a ribbon of a cone in the primate fovea has ~40 docking sites close to the active zone and 150 vesicles are packed along the ribbon (Sterling, P. and Matthews, G., 2005). The vesicles of all cones and of rods are loaded with glutamate through the vesicular glutamate transporter vGluT1 (Haverkamp, S.

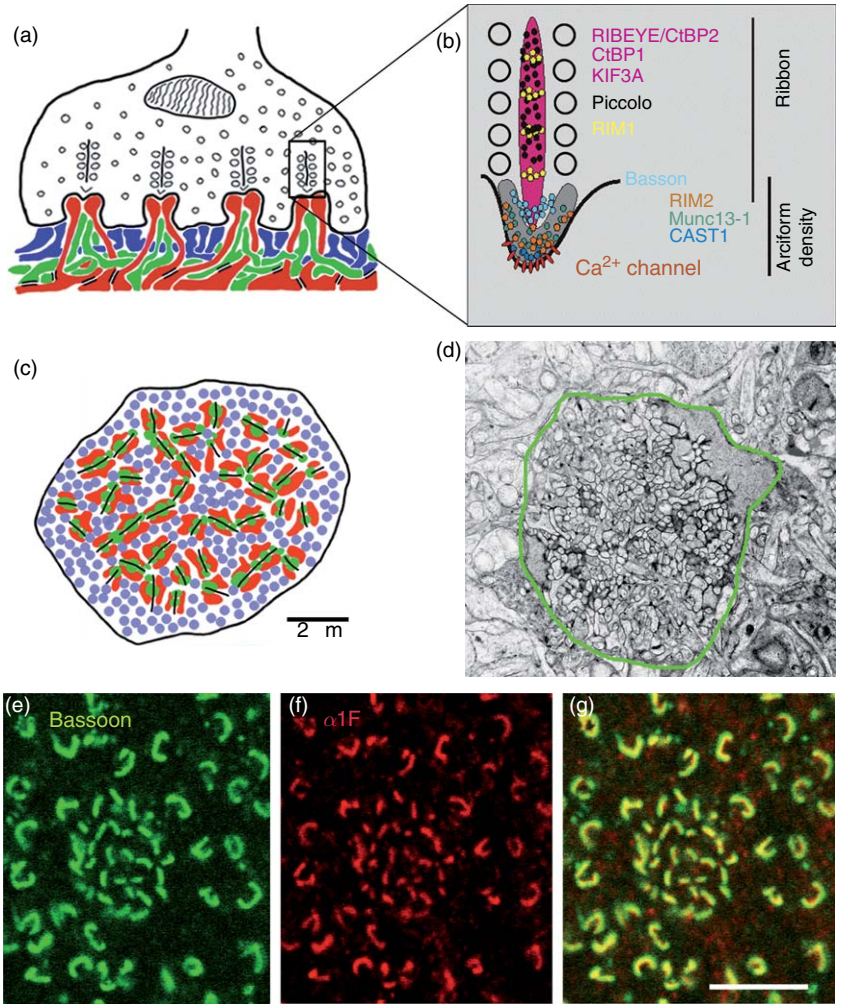

Figure 1 Structure of the cone pedicle, the synaptic terminal of cones. (a) Schematic vertical view of a cone pedicle. Four presynaptic ribbons are apposed to the invaginating dendrites of horizontal cells (red) and ON-cone bipolar cells (green). OFF-cone bipolar cell dendrites form contacts at the cone pedicle base (blue). (b) The presynaptic compartment is made up of the ribbon, the vesicles, and the arciform density. Adapted from tom Dieck, S., Altrock, W. D., Kessels, M. M., Qualmann, B., Regus, H., Brauner, D., Fejtova, A., Bracko, O., Gundelfinger, E. D., and Brandstätter, J. H. 2005. Molecular dissection of the photoreceptor ribbon synapse: physical interaction of Bassoon and RIBEYE is essential for the assembly of the ribbon complex. J. Cell Biol. 168, 825–836. The following proteins are associated with the ribbon: RIBEYE (Schmitz, F. *et al.*, 2000); CtBP1,2; KIF3A (Muresan, V. *et al.*, 1999); Piccolo; RIM1. The following proteins are associated with the arciform density: Bassoon; RIM2; Munc 13-1; CAST. The Ca^{2+} channels are inserted into the presynaptic membrane (Morgans, C. W. *et al.*, 2005). (c) Schematic horizontal view of a macaque monkey (primate) cone pedicle base. Ribbons (black lines), horizontal cell processes (red), and ON-cone bipolar cell dendrites (green) form a total of 40 triads. Numerous contacts of OFF-cone bipolar cells (blue) are found throughout the pedicle base. (d) Electron micrograph of a horizontal section taken underneath a primate cone pedicle (green outline). More than 500 individual processes contact this cone pedicle. (e–g) Fluorescence micrographs of a primate cone pedicle (center) surrounded by rod spherules, double labeled for bassoon (e) and the Ca^{2+} channel subunit α1F (f). Bassoon immunolabeling decorates the ribbons of the cone pedicle and the rod spherules (horseshoe-shaped). The superposition of (e) and (f) in (g) shows that the Ca^{2+} channels are in close vicinity of the synaptic ribbons. Scale bar = 5 μm.

et al., 2003; Johnson, J. *et al.*, 2003; Sherry, D. M. *et al.*, 2003). A subpopulation of approximately 10% of cones expresses vGluT2 in addition to vGluT1 (Fyk-Kolodziej, B. *et al.*, 2004; Wässle, H. *et al.*, 2006).

Exocytosis of the vesicles is finally triggered by voltage-gated Ca^{2+} channels clustered at the active zone. Immunostaining for the α1D and α1F subunits of L-type Ca^{2+} channels and Ca^{2+} entry have

been observed along the base of the ribbon (Figures 1(e)–1(g); Morgans, C. W., 2001; Wässle, H. *et al.*, 2003; Zenisek, D. *et al.*, 2003; 2004; tom Dieck, S. *et al.*, 2005). Mutations in the Ca^{2+} channel α1F result in impairment of the photoreceptor synaptic transmission and cause congenitory stationary nightblindness (Morgans, C. W. *et al.*, 2005). Ca^{2+} extrusion from the photoreceptor synaptic complex is mediated through the plasma membrane calcium ATPase (PMCA) localized along the sides of cone pedicles and rod spherules (Morgans, C. W. *et al.*, 1998; Duncan, J. L. *et al.*, 2006).

The potassium (K^+-) and Ca^{2+}-channels of cone pedicles and rod spherules can be modulated by several mechanisms which in turn also regulate the transmitter release. The metabotropic glutamate receptor 8 (mGluR8) at the photoreceptor synaptic terminals, acts as autoreceptor and upon glutamate binding the influx of Ca^{2+} is reduced (Koulen, P. *et al.*, 1999; 2005). Modulation of the voltage dependent Ca^{2+}-channels at the active zone is also a mechanism of horizontal cell feed back and will be discussed later. Cannabinoid receptors at cone pedicles regulate voltage-dependent K^+ currents (Struik, M. L. *et al.*, 2006). Finally, calcium extrusion modulates the amplitude and timing of transmission in cone pedicles and rod spherules (Duncan, J. L. *et al.*, 2006).

L- and M-cone pedicles are coupled to their immediate neighbors and to rod spherules through electrical synapses (gap junctions; Raviola, E. and Gilula, N. B., 1973) where connexin 36 is expressed. S-cone pedicles are only sparsely coupled (Tsukamoto, Y. *et al.*, 2001; Feigenspan, A. *et al.*, 2004; Hornstein, E. P. *et al.*, 2004; Li, W. and DeVries, H., 2004, O'Brien, J. J. *et al.*, 2004). This coupling allows the network to average out the uncorrelated noise in individual cones, and thereby to improve the response to a light stimulus (Lamb, T. D. and Simon, E. J., 1976). It also provides a route for the signal transfer from rod spherules to cone pedicles (see Mammalian Rod Pathways and Circuit Functions of Gap Junctions in the Mammalian Retina).

1.12.2.2 The Postsynaptic Partners

At the synaptic terminals of rods and cones, the light-evoked signals are transferred onto bipolar and horizontal cells (Figure 1(a)). Horizontal cells, of which there are between one and three types in mammalian retinas, provide lateral interactions in the outer plexiform layer (OPL). In the primate retina they are named H1 and H2 horizontal cells. Their dendritic tips are inserted into invaginations of the cone pedicle base which are formed at the ribbons. Two horizontal cell endings push up towards the ribbon and along the ribbon the two horizontal cells form a zone of contact between each other (Raviola, E. and Gilula, N. B., 1975).

Two kinds of bipolar cell contacts have been identified at cone pedicles: flat or basal contacts and invaginating contacts (Dowling, J. E. and Boycott, B. B., 1966). The dendritic tips of invaginating bipolar cells are inserted in between the two lateral horizontal cell dendrites, and this postsynaptic unit has been named a triad (Missotten, L., 1965). The dendritic tips of flat bipolar cells make numerous contacts at the cone pedicle base (Figures 1(a) and 1(c)).

Cone pedicles of the peripheral primate retina contain ~40 synaptic ribbons and invaginations, where they accommodate ~80 horizontal cell dendritic terminals (Figure 1(c)). L (red)- and M (green)-cones are connected to three or four H1 horizontal cells and make multiple contacts with every one of them. S (blue)-cones have only sparse, if any connections with H1 horizontal cells. L- and M-cones are also connected to three or four H2 horizontal cells, however, the number of contacts is smaller than with H1 cells. In contrast, S-cones have multiple contacts with H2 cells (Ahnelt, P. and Kolb, H., 1994). Cone pedicles of the peripheral primate retina accommodate ~80 dendritic tips of invaginating bipolar cells (Chun, M. H. *et al.*, 1996) and they are engaged in 200–300 flat contacts. Taken together, 400–500 synaptic contacts are found at individual cone pedicles (Figure 1(d)). Their details will be discussed later.

1.12.2.3 Feedback from Horizontal Cells

Horizontal cell dendrites are inserted as lateral elements into the invaginating contacts of cone pedicles (Figure 1(a)), and horizontal cell axon terminals form the lateral elements within rod spherules. Traditionally, it is assumed that horizontal cells release the inhibitory transmitter gamma-aminobutyric acid (GABA) and provide feedback inhibition at the photoreceptor synaptic terminal. As horizontal cells summate light signals from several cones, such feedback would cause lateral inhibition, through which a cone's light response is reduced by the illumination of neighboring cones. This mechanism is thought to enhance the response to the edges of visual stimuli and to reduce the response to areas of uniform brightness. However, the GABA-feedback model has recently been challenged because of the

lack of classical synapses from horizontal cells onto cones, the lack of GABA receptors on mammalian cones and the lack of GABA uptake into horizontal cells from the medium. Two alternative hypotheses of horizontal cell function have been proposed. One assumes that horizontal cell processes, which are inserted into cone pedicles and rod spherules, express connexins (hemigap junctions). Current that flows through the channels formed by the connexins changes the extracellular potential in the invaginations and thus shifts the activation curves of the cone pedicle Ca^{2+} channels. By this mechanism of electrical feedback, horizontal cells could modulate the glutamate release from cones and rods (Kamermans, M. *et al.*, 2001). The second hypothesis also postulates modulation of the Ca^{2+} channels that regulate the release of glutamate from cones; however, the mechanism responsible is a change in pH within the invagination, caused by voltage-dependent ion transport through the horizontal cell membrane (Hirasawa, H. and Kaneko, A., 2003). There is also evidence that light-dependent release of GABA from horizontal cells provides feed-forward inhibition of bipolar cell dendrites (Haverkamp, S. *et al.*, 2000; Duebel, J. *et al.*, 2006). Irrespective of their precise mode of action, horizontal cells sum light responses across a broad region, and subtract it from the local signal. Because horizontal cells are coupled through gap junctions (see Circuit Functions of Gap Junctions in the Mammalian Retina), their receptive fields can be much wider than their dendritic fields (Hombach, S. *et al.*, 2004).

1.12.3 Morphological Types of Bipolar Cells

Bipolar cells of the mammalian retina can be subdivided according to their morphology into many different types (Figure 2). Cajal S. R. Y. (1893) recognized rod bipolar (RB) cells as a separate type (Figure 2: RB). Their dendrites make invaginating contacts with rod spherules and their axons terminate in the innermost part of the IPL (see Mammalian Rod Pathways). Several types of cone bipolar cells have been recognized in different mammalian species. In the rabbit retina 13 types have been described from Golgi staining and single cell filling (Famiglietti, E. V., 1981; McGillem, G. S. and Dacheux, R. F., 2001; MacNeil, M. A. *et al.*, 2004). In the cat retina 8–10 different types of cone bipolar cells have been recognized (Famiglietti, E. V., 1981; Kolb, H. *et al.*, 1981; Cohen, E. D. and Sterling, P., 1990a; 1990b). In the ground squirrel seven different types have been described (West, R. W., 1976).

The diagram in Figure 2 compares the bipolar cells of the mouse and rat retinas with those of the peripheral macaque monkey retina. The nine putative cone bipolar cell types (labeled 1–9) and the RB cells of the mouse and rat retina are arranged according to the stratification level of their axon terminals in the IPL. The cells were drawn from vertical sections following intracellular injections (Euler, T. and Wässle, H., 1995; Hartveit, E., 1996; Ghosh, K. K. *et al.*, 2004; Pignatelli, V. and Strettoi, E., 2004). Immunocytochemical markers have been found for five bipolar cell types of the mouse retina (Haverkamp, S. *et al.*, 2003; illustrated in Figure 3). The type 7 and type 9 bipolar cells of the mouse retina have also been labeled in transgenic mouse lines by the expression of green fluorescent protein (GFP; Huang, L. *et al.*, 2003; Haverkamp, S. *et al.*, 2005). The cone contacts of the nine bipolar cell types of mouse and rat have not yet been analyzed in detail, however, they contact between five and 10 neighboring cone pedicles with one exception: type 9 has a wide dendritic tree that appears to be cone selective and it will be shown later that it contacts S-cones.

Rat and mouse retinas are considered to be rod dominated because only 1% of their photoreceptors are cones (Szél, A. *et al.*, 1993). However, the perspective changes if one examines the absolute number of cones. The cone density is between 8000 and 10 000 cones mm^{-2}, comparable to midperipheral cat, rabbit, and monkey retina. Consequently the types and retinal distributions of cone bipolar cells are closely similar between mammalian species. The bipolar cells of the monkey retina, shown schematically in Figure 2, where determined initially from Golgi stained whole mounts (Boycott, B. B. and Wässle, H., 1991). There is a striking similarity between mouse, rat, and monkey bipolar cells with respect to the shapes and stratification levels of their axons, however, there is also a clear difference; midget bipolar cells (flat midget bipolar, FMB; invaginating midget bipolar, IMB) are only found in the monkey retina. FMB and IMB cells have dendritic trees which contact a single cone (Polyak, S. L., 1941; Figure 2 and Figure 4(a)). Following the nomenclature of Polyak S. L. (1941), bipolar cells contacting several neighboring cone pedicles were named diffuse bipolar cells (DB1–DB6; Boycott, B. B. and Wässle, H. 1991; Figures 2 and 4(c)).

In summary these studies suggest that there are about 10 types of cone bipolar cells in the mammalian

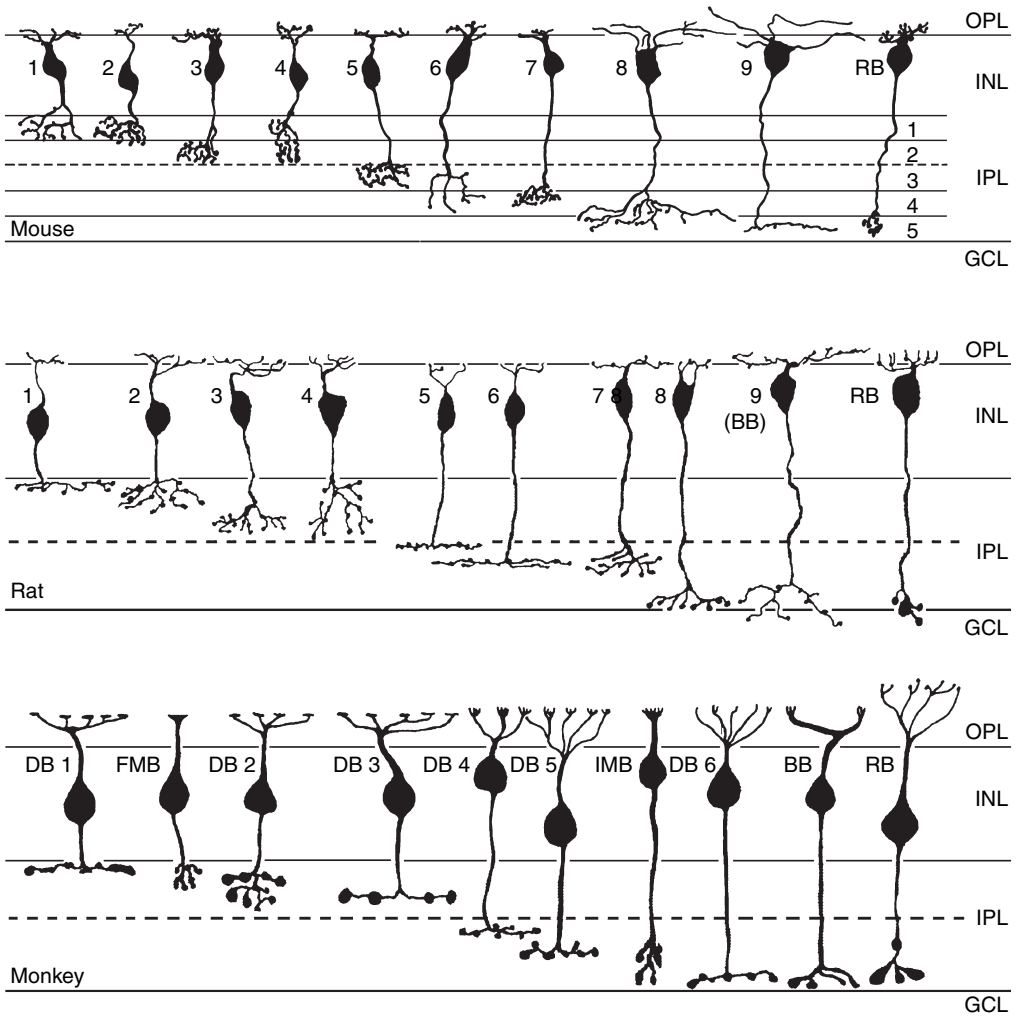

Figure 2 Schematic diagrams of bipolar cells of mouse, rat, and primate retina (Ghosh, K. K. *et al.*, 2004). The retinal layers are indicated (OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; it can be subdivided into five sublaminas of equal width; GCL, ganglion cell layer). The bipolar cell types were named according to the level of stratification of their axon terminals in the IPL. The dashed horizontal lines dividing the IPL represent the border between the OFF- (upper) and the ON- (lower) sublayers. Bipolar cells with axons terminating above this line represent OFF bipolar cells, those with axons terminating below this line represent ON bipolar cells (DB, diffuse bipolar cells; FMB, flat midget bipolar cells; IMB, invaginating midget bipolar cells; BB, blue-cone bipolar cells; RB, rod bipolar cells).

retina and their major defining features are the shape and stratification of their axons in the IPL and in some instances their cone contacts in the OPL (Hopkins, J. M. and Boycott, B. B., 1996; 1997). The major functional subdivision of bipolar cells is into ON- and OFF-bipolar cells. ON-bipolar cells are depolarized by a light stimulus, OFF-bipolar cells are hyperpolarized by a light stimulus (Werblin, R. S. and Dowling, J. E., 1969; Kaneko, A., 1970). Their axons terminate at different levels (strata) within the IPL: OFF in the outer half, ON in the inner half (Euler, T. *et al.*, 1996; Hartveit, E., 1996; Euler, T. and Masland, R. H., 2000; Berntson, A. and Taylor, W. R., 2000). Superimposed on this ON/OFF dichotomy are four types of OFF and five types of ON-cone bipolar cells. We are just beginning to understand their functional roles (Freed, M. A., 2000).

1.12.3.1 Midget Bipolar Cells of the Primate Retina

Before discussing the function of midget bipolar cells, the distribution of cells across the retina (topography) has to be considered (Wässle, H. and Boycott, B. B.,

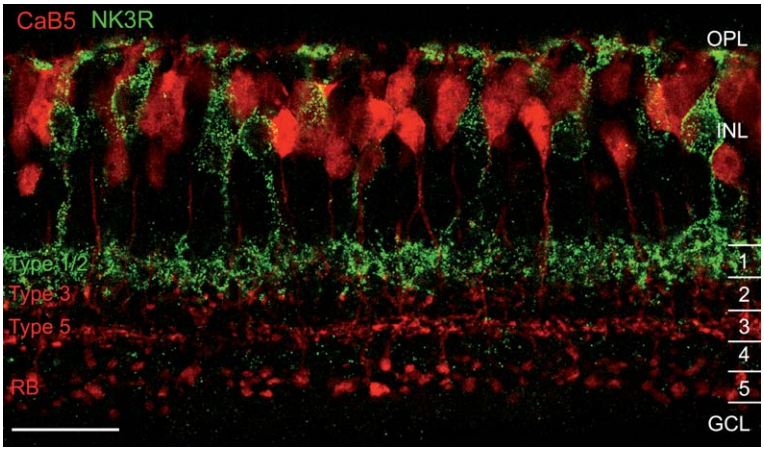

Figure 3 Immunocytochemical staining of mouse bipolar cells. Fluorescence micrograph of a vertical section through mouse retina double immunostained for the calcium-binding protein 5 (CaB5, red) and the neurokinin receptor 3 (NK3R, green). Three bipolar cell types (type 3, type 5 and RB express CaB5. Their axons terminate in the inner plexiform layer inner plexiform layer in sublamina 2, sublamina 3, and sublamina 5, respectively. Type 1/2 bipolar cells express NK3R and their axons are restricted to sublamina 1. GCL, ganglion cell layer; INL, inner nuclear layer; OPL, outer plexiform layer; RB, rod bipolar. Scale bar = 20 μm.

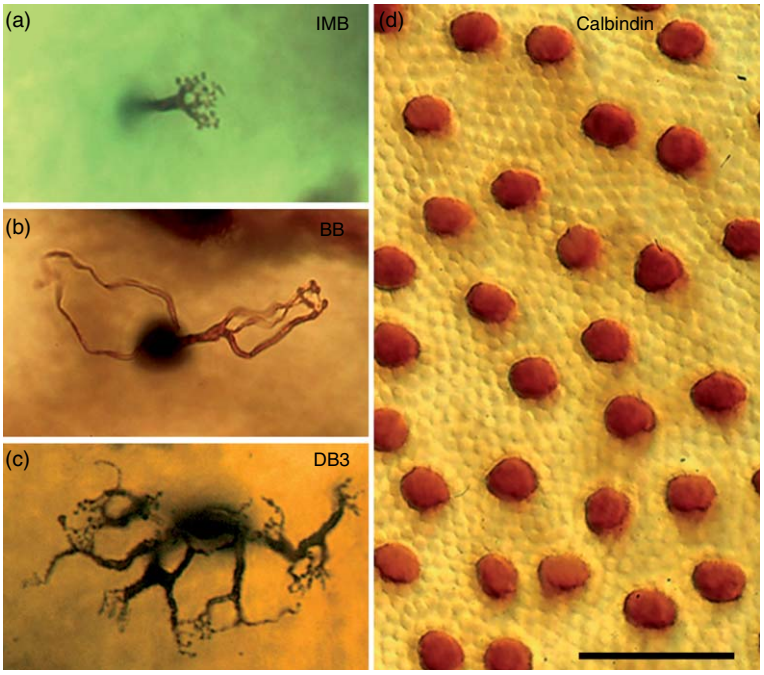

Figure 4 Bipolar cells and their cone contacts in the primate retina. Horizontal view of Golgi stained bipolar cells, with the plane of focus at their dendritic tips in the outer plexiform layer. (a) Dendritic tips of a invaginating midget bipolar cell (IMB). The micrograph in (d) shows the cone pattern (immunolabeled for the calcium-binding protein calbindin) at a comparable eccentricity, and the dendritic tips of the IMB cell in (a) are restricted in size to a single cone. (b) Dendritic branches of a blue-cone bipolar (RB) cell, which contact two widely spaced cones. Comparison with the cone pattern in (d) shows that this BB cell is cone-selective. (c) Dendritic branches of a diffuse bipolar cell (DB3) that would contact altogether nine neighboring cone pedicles. Scale bar = 20 μm.

1991). In the peripheral retina, there is a low density of cones, bipolar cells, and ganglion cells, whereas toward the center of the retina (the central area of cats, the visual streak of rabbits, or the fovea of primates) the density of these cells increases steeply. This results in greatly improved spatial resolution (visual acuity) at the fovea or central area. Concomitant with the increase in density, the cells' dendritic fields become smaller. During evolution, the spatial resolution of the primate eye and retina has been optimized. To achieve this, a high cone density and a low cone-to-RGC ratio have converged in the acuity pathway. The anatomic limits for this optimization are reached when each cone is connected through a midget bipolar cell to a midget ganglion cell, establishing a private line to the brain (Figures 4(a) and 4(d)). It has been suggested that only after this one-to-one connection in the central retina had evolved, 35 million years ago, did a subsequent mutation in the L-cone pigment create L- and M-cones of varying proportions at random spatial locations (Mollon, J. D. and Jordan, G., 1988; Mollon, J. D., 1989; Wässle, H. and Boycott, B. B., 1991; Boycott, B. B. and Wässle, H., 1999; Nathans, J., 1999). The midget system of the central retina was able to transmit this chromatic information to the brain where it could be used, for example to detect red fruit among green leaves. Recently it became possible to study the L-/M- and S-cone mosaics of the living human retina by the application of adaptive optics (Hofer, H. *et al.*, 2005). This revealed the irregular arrangement of L- and M-cones. Moreover it showed that the relative proportions of L- and M-cones greatly varied between human individuals (Roorda, A. and Williams, D. R., 1999). The midget system is able to transfer this irregular mosaic to the brain which apparently can compensate such variability, and color vision in human individuals is not affected by the different ratios of M- and L-cones (Neitz, J. *et al.*, 2002).

This midget theory of the evolution of trichromacy in primates has its basis in the general pattern of mammalian wiring. It is not necessary to postulate, in addition, specific mutations to change the cone selectivity of bipolar cells, the cone selectivity of GluRs, or the selectivity of ganglion cells (Calkins, D. J. and Sterling, P., 1999). It also explains why mammals other than primates have not evolved trichromacy: their cone bipolar cells sum the signals of several cones, and their RGCs sum the signals of many bipolar cells. A mutation that created M- and L-cones would be lost in this convergent network, which pools signals from many cones (Wässle, H., 1999). A recent transgenic mouse expressing human L- and M-opsins was not able to perform trichromatic color discrimination (Jacobs, G. H. *et al.*, 2004). However, in a further transgenic mouse where large patches of the cone mosaic expressed either L- or M-opsins trichromatic color discrimination was possible (Smallwood, P. M. *et al.*, 2003; Jacobs, G. H. *et al.*, 2007). The idea that trichromacy piggy-backs on the high acuity system of primates also postulates that the midget bipolar cells perform a double duty in visual signaling, acuity and trichromacy, an idea that has been promoted for some years (Ingling, C. R., Jr. and Martinez-Uriegas, E., 1983a; 1983b).

1.12.3.2 Blue-Cone Bipolar Cells

Placental mammals other than primates have only two types of cone: L-cones in which the visual pigment has an absorption maximum of greater than 500 nm and S-cones with an absorption maximum at less than 500 nm. They are, therefore, dichromats. In an evolutionary comparison of color pigments it has been estimated that the separation of the L- and S-cone pigments occurred more than 500 million years ago and thus represents the phylogenetically ancient, primordial color system (Mollon, J. D., 1989). The morphological substrate for the dichromatic color vision common to most placental mammals is the S-cone pathway (Calkins, D. J., 2001). Mariani A. P. (1983; 1984) described bipolar cells selective for S-cones in the macaque monkey retina. They have long, smoothly curved dendrites and contact between one and three cone pedicles (Figures 4(b) and 4(d)). Their axons terminate in rather large varicosities in the innermost part of the IPL, close to the ganglion cell layer (BB-cells in Figure 2). S-cone bipolar cells have been quantified by selective labeling with antibodies against cholecystokinin (CCK; Kouyama, N. and Marshak, D. W., 1992; Wässle, H. *et al.*, 1994). Their selective innervation of S-cones has been shown in old world and new world primates (Ghosh, K. K. *et al.*, 1997; Calkins, D. J. *et al.*, 1998), and it has been shown that they provide input to the inner tier of the dendritic tree of the small bistratified ganglion cells (Calkins, D. J. *et al.*, 1998). Small bistratified ganglion cells give blue-ON, yellow-OFF responses (Dacey, D. M. and Lee, B. B., 1994). In the retina of the ground squirrel light responses of a S-cone selective bipolar cell have been recorded and this bipolar cell was an ON-bipolar cell (Li, W. and DeVries, H., 2006).

Immunostaining with antisera specific for S-opsin has shown that S-cones constitute approximately 10% of the cones in most mammalian retinas (Szél, A. *et al.*,

1988; 1993). However, in some species S-cones have a very uneven topographical distribution across the retina and many cones express both L- and S-opsin (Glösmann, M. and Ahnelt, P. K., 1998; Applebury, M. L. *et al.*, 2000; Lukáts, A. *et al.*, 2005). So far only circumstantial evidence for the existence of S-cone selective bipolar cells in mammals other than primates has been presented (rabbit: Famiglietti, E. V., 1981; Jeon, C. J. and Masland, R. H., 1995; cat: Cohen, E. D. and Sterling, P., 1990a; 1990b; ground squirrel; West, R. W., 1976; rat: Euler, T. and Wässle, H., 1995; mouse: Ghosh, K. K. *et al.*, 2004; Pignatelli, V. and Strettoi, E., 2004). However, recently a transgenic mouse line could be studied, where Clomeleon, a genetically encoded fluorescence indicator, was expressed under the *thy1* promotor (Haverkamp, S. *et al.*, 2005). Clomeleon labeled ganglion cells, amacrine cells, and bipolar cells. Among the bipolar cells the S-cone-selective (blue cone) type could be identified, and the cone-selective contacts and the retinal distribution could be studied. The morphological details of the blue-cone bipolar cell match type 9 cells of rat and mice (Figure 2) and they are closely similar to the blue-cone bipolar cell of the primate retina (Figure 4(b)). It is interesting that in the ventral mouse retina, where most cones express both L- and S-opsin, blue-cone bipolar cells contact only those cones, which express S-opsin only, and they are the genuine blue cones of the mouse retina (Haverkamp, S. *et al.*, 2005).

1.12.3.3 Diffuse Bipolar Cells

Most bipolar cell types of the mammalian retina contact between five and seven neighboring cones (Figures 4(c) and 4(d)). Diffuse bipolar cells of the primate retina contact L- and M-cones in their dendritic field nonselectively (Boycott, B. B. and Wässle, H., 1991). They are, therefore, involved with the transfer of a luminosity signal, which is based on the combined sensitivity of L- and M-cones (Lee, B. B. *et al.*, 1990). Whether all diffuse bipolar cell types also contact S-cones is still a matter of discussion and it has been proposed that one type of diffuse bipolar cell avoids S-cones (Calkins, D. J. *et al.*, 1996). This type would be a good candidate to transfer a yellow (L-plus M-cone) signal into the IPL, where it could contact the outer tier of the dendritic tree of the small bistratified ganglion cells (Dacey, D. M. and Lee, B. B., 1994). Recordings from diffuse bipolar cells of the retina of the ground squirrel show that there are two groups of diffuse bipolar cells: one receives mixed input from S- and M-cones, while the other one receives an almost pure M-cone signal (Li, W. and DeVries, H., 2006).

1.12.3.4 Cone Contacts of Bipolar Cells

The cone pedicle has two kinds of synaptic specializations, which are occupied by bipolar cells: invaginating and flat contacts (Figure 1(a)). Reconstructions of Golgi-impregnated midget bipolar cells of the primate retina by serial electron microscopy (EM; Figure 5) showed a clear dichotomy: IMB cells made exclusively invaginating contacts, whereas FMB cells made only flat contacts (Kolb, H., 1970). Individual IMB cells make up to 25 contacts with a cone pedicle (Figure 5(a)), an FMB cell makes approximately 2.0–3.5 times that number of basal synapses (Hopkins, J. M. and Boycott, B. B., 1996; 1997). Most of the contacts of FMB cells are in the vicinity of the ribbons (Figure 5(b), triad associated, TA). Reconstructions of cone contacts of Golgi-impregnated diffuse bipolar cells by EM revealed that DB1, DB2, and DB3, which have their axon terminals in the outer IPL and are putative OFF bipolar cells, make exclusively basal junctions with the cone pedicle (Figure 5(c)). They always have TA and nontriad associated (NTA) contacts, the proportions varying according to the cell type, as does the average number of contacts per cone, which is between 10 and 20. Bipolar cells DB4, DB5, and DB6 have their axon terminals in the inner part of the IPL and are putative ON bipolar cells. They have an average of between four and eight invaginating synapses per cone pedicle. In addition they also form basal junctions, in a predominantly TA position (Hopkins, J. M. and Boycott, B. B., 1996; 1997). Thus, while the dichotomy invaginating = ON, flat = OFF holds for midget bipolar cells, it does not conform so clearly for diffuse bipolar cells. As discussed later, the type of synapse made by a bipolar cell at a cone pedicle, flat versus invaginating, is not the decisive feature; it is rather the GluR expressed there.

Recent results from the rodent and the rabbit retina have shown that some OFF-cone bipolar cells make also basal contacts with rod spherules and thus receive a direct input from rods (Hack, I. *et al.*, 1999; Tsukamoto, Y. *et al.*, 2001; Li, W. *et al.*, 2004; Protti, D. A. *et al.*, 2005). This represents a third route for the rod signal in addition to the RB cell circuit and the gap junctions between rods and cones (Volgyi, B. *et al.*, 2004).

The number of contacts per cone pedicle of a given diffuse bipolar cell varies across its dendritic field (Figure 5(c)). More contacts are made with cones in the center, and only few contacts are made

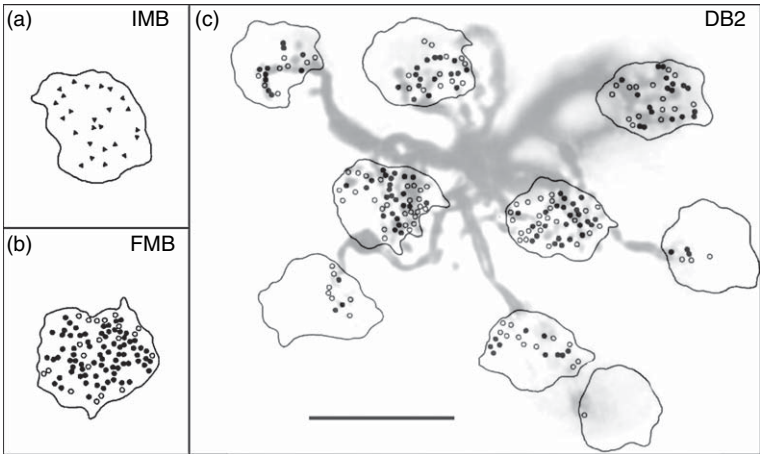

Figure 5 Cone contacts of bipolar cells of the primate retina. The cells were Golgi-stained and afterwards serially sectioned for electron microscopic analysis (Hopkins, J. M. and Boycott, B. B., 1996). (a) The 25 contacts of an invaginating midget bipolar cell are all invaginating. (b) The 97 contacts of a flat midget bipolar cell are all flat (●, triad associated; ○, nontriad associated). (c) reconstruction of the cone contacts of a diffuse bipolar cell DB2. The dendritic tree, as revealed by the Golgi staining, is inserted. This DB2 cell connects to nine cone pedicles, exclusively with flat contacts. Scale bar = 20 μm. Adapted from Boycott, B. B. and Wässle, H. 1999. Parallel processing in the mammalian retina: the Proctor Lecture. Invest. Ophthalmol. Vis. Sci. 40, 1313–1327.

with more peripheral cones, which predicts a Gaussian sensitivity profile. The dendrites of neighboring bipolar cells of a given type show different extents of overlap and their coverage factor is between one and four. This means that a cone pedicle may contact one to four bipolar cells of any given type. This is illustrated in Figure 6 for type 7 bipolar cells of a transgenic mouse line which expresses GFP under the control of the gustducin promotor (Huang, L. *et al.*, 2003). They were immunostained for GFP (Figure 6(a)) and their dendritic network (Figures 6(b) and 6(d)), cell bodies, and axon terminals (Figures 6(c) and 6(e)) are shown. The positions of cone pedicles are marked by the expression of GluR5 (Haverkamp, S. *et al.*, 2005). Analysis of individual bipolar cells in this network shows that bipolar cells contact approximately eight cone pedicles (convergence) and cone pedicles are innervated by approximately one bipolar cell (divergence). The cone density in this area is 13 000 mm^{-2}, the density of this bipolar cell type is 2000 mm^{-2}. Type 7 bipolar cells represent approximately 10% of the total cone bipolar cell population of the mouse retina. Some of the axon terminals are delineated by red circles in Figure 6(e) and it is obvious that they are precisely space filling, without any overlap. They are all within the same focal plane and therefore confined to a narrow stratum within the IPL (Figure 6(a)). This example shows the dendritic and axonal architecture of a defined bipolar cell type, and thus represents one of the parallel routes from the outer to the IPL.

1.12.4 Expression of Glutamate Receptors at Cone Pedicles

1.12.4.1 Glutamate Receptor Subunits

Molecular cloning has revealed a multiplicity of GluRs and receptor subunits. Ionotropic receptors are integral membrane proteins that form an ion channel. This channel, usually a nonselective cation channel, is made up of four subunits and opens upon glutamate binding. Three major groups of ionotropic GluRs can be distinguished: α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), kainate, and *N*-methyl-D-aspartate (NMDA) receptors. They comprise the following subunits: AMPA (GluR1, GluR2, GluR3, GluR4); kainate (GluR5, GluR6, GluR7, KA-1, KA-2); NMDA (NR1, NR2A, NR2B, NR2C, NR2D and NR3A); further subunits are the orphan receptors δ1 and δ2. In addition multiple splice variants of the different subunits, have been identified, for example, the 10 splice variants of NR1 (Hollmann, M. and Heinemann, S., 1994; Dingledine, R. *et al.*, 1999; Kew, J. N. C. and Kemp, J. A., 2005). mGluRs belong to the family of receptors that have seven membrane-spanning domains and, when they

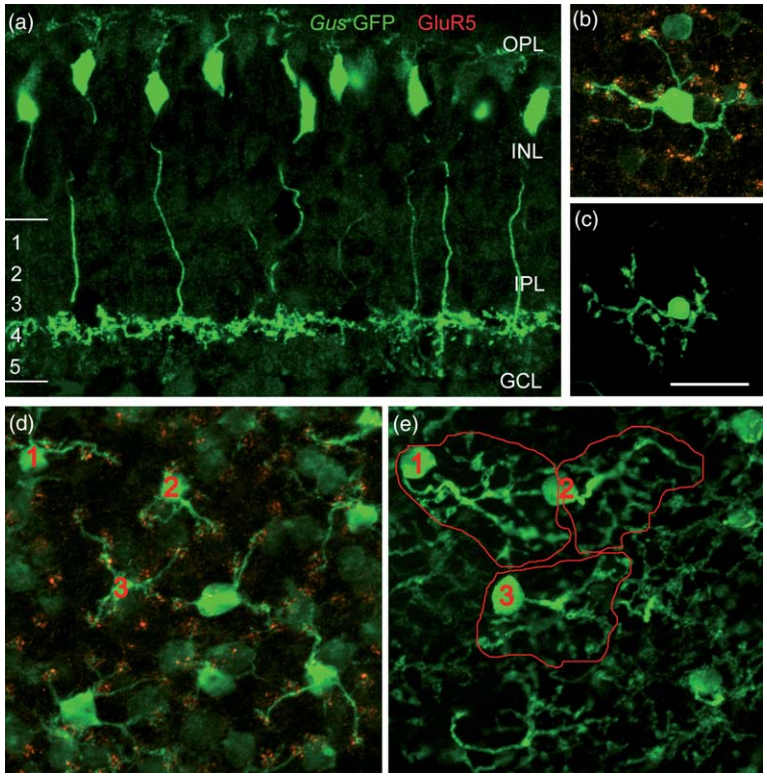

Figure 6 Array of type 7 bipolar cells of the mouse retina. The cells express green fluorescent protein (GFP) under the control of the α-gustducin promotor (Huang, L. *et al.*, 2003). (a) Fluorescence micrograph of a vertical section showing strong expression of GFP in type 7 bipolar cells their axon terminals in sublamina 3/4 of the inner plexiform layer (IPL). Faint expression can also be detected in some rod bipolar cell axon terminals in sublamina 5. (b, c) Horizontal view of the dendritic field and the axon terminal of an isolated type 7 bipolar cell. The dendrites in (b) contact all 12 cone pedicles within the dendritic field. They are labeled by the expression of the kainate receptor GluR5 (clusters of red dots). The axon terminal in (b) covers an area of $\sim$500 μm^2. (d, e) Horizontal view a patch of retina, where apparently all type 7 cells are labeled. Their dendritic trees in (d) contact an average number of 8.1 $\pm$ 1.3 ($n = 20$) cone pedicles (convergence). Dendritic fields of neighboring type 7 cells in this field show practically no overlap and, therefore, most cone pedicles are in contact with only one type 7 bipolar cell (divergence). The axon terminals of the type 7 bipolar cells in the IPL are space filling without much overlap (coverage of 1). This is indicated by the red outlines for three selected cells. GCL, ganglion cell layer; INL, inner nuclear layer; OPL, outer plexiform layer. Scale bar = 20 μm for (a), 17 μm for (b) and (c), 16 μm for (d) and (e).

bind glutamate, G protein, and second messenger systems are activated. So far eight different mGluRs have been identified (mGluR1–mGluR8). It is clear that a simple retinal scheme: glutamate released from photoreceptors acts on horizontal and bipolar cells and then, in turn glutamate released from bipolar cells activates amacrine and ganglion cells, can have any degree of complexity depending on the GluRs that are expressed.

1.12.4.2 ON-Bipolar Cell Glutamate Receptors

In a series of seminal experiments, Nakanishi and co-workers have cloned mGluR6, localized it with specific antibodies, and studied the function by gene directed (knockout) mutagenesis (Nomura, A. *et al.*, 1994; Masu, M. *et al.*, 1995). These experiments have shown that mGluR6 is expressed at the dendritic terminals of RB cells inserted into the rod spherules. In the mGluR6 knockout mouse, all ON-light responses were blocked (Masu, M. *et al.*, 1995; Renteria, R. C. *et al.*, 2003). Vardi N. *et al.* (1998) have shown that mGluR6 also is expressed in ON-cone bipolar cells at their invaginating, and occasionally flat, contacts with cone pedicles. Previous pharmacological studies had shown that light responses of all ON-bipolar cells are blocked by 2-aminophosphonobutyric acid (LAP-4; Slaughter, M. M. and Miller, R. F., 1981), a glutamate agonist at mGluR (group III) receptors (Pin, J. P. and Duvoisin, R., 1995). The signal cascade activated through

mGluR6 in ON-bipolar cells involves the G protein G alpha (o) (Dhingra, A. *et al.*, 2002; 2004), however, the membrane channel modulated by the cascade has not yet been identified (Nawy, S., 1999; Snellman, J. and Nawy, S., 2004). Recently a transgenic mouse was created, where the mGluR6 promotor drives the expression of GFP and all ON-bipolar cells were found to be labeled (Morgan, J. L. *et al.*, 2006). Taken together this shows that mGluR6 is the predominant GluR expressed in all ON-bipolar cells. However, it has to be emphasized that additional GluRs have been localized to them and their functions still need to be elucidated (Koulen, P. *et al.*, 1997; Vardi, N. *et al.*, 1998; Lo, W. *et al.*, 1998; Calkins, D. J., 2005). It is possible that they fulfill some modulatory roles in different ON bipolar cell types.

1.12.4.3 OFF-Bipolar Cell Glutamate Receptors

Immunocytochemical localization of GluR subunits to flat contacts of bipolar cells at the cone pedicle base has revealed a plethora of different GluRs. The AMPA receptor subunit GluR1 has exclusively been observed in flat contacts and has not been found in horizontal cell processes (Brandstätter, J. H., 2002). In retinas double labeled for the ribbon marker bassoon and for GluR1, GluR1 hot spots are located in close vicinity of the ribbons, suggesting a TA position (Figures 7(d)–7(f); Haverkamp, S. *et al.*, 2001). In the macaque monkey retina it was possible to compare the GluR1 expression of M/L- and S-cones. The same number of GluR1 hot spots was observed, however, they were more salient in S-cone pedicles (Haverkamp, S. *et al.*, 2001). Whether this represents a higher density of GluR1 expression at S-cones, or whether the hot spots are more closely packed at the smaller S-cone pedicles cannot be answered at present. Puller C. *et al.* (2007) could show that FMB cells of the primate retina express GluR1 at their contacts with cone pedicles. FMB cells have been shown to contact M/L- as well as S-cones in the macaque monkey retina (Klug, K. *et al.*, 2003). GluR1-labeled flat contacts have also been observed in the rodent

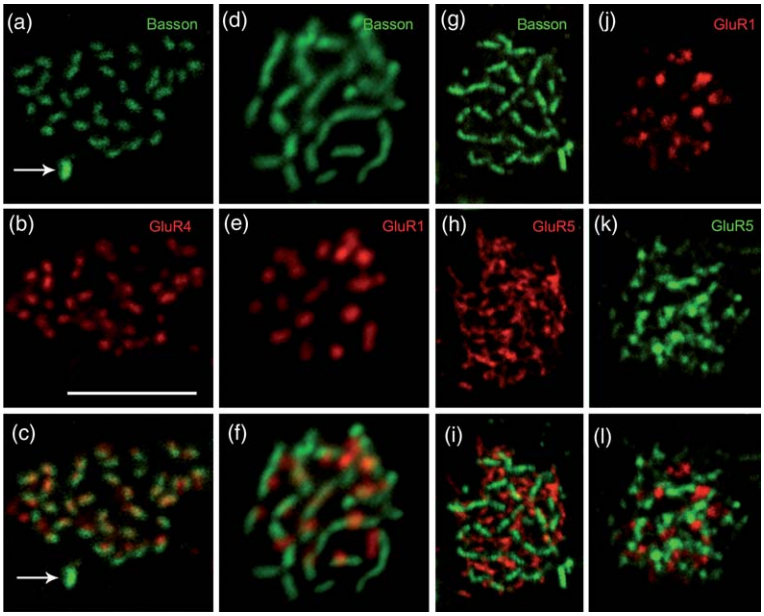

Figure 7 Horizontal confocal sections of cone pedicles of the primate retina that were double labeled for bassoon and glutamate receptor subunits (GluRs). (a) The ribbons of one cone pedicle and one rod spherule (arrow) are immunoreactive for bassoon (green). (b) GluR4 immunoreactive hot spots of the same section as in (a) (red). (c) Superposition of (a) and (b) shows that most of the GluR4 immunoreactive hot spots are in register with the ribbons. (d) Cone pedicle from the more central retina immunolabeled for bassoon. (e) GluR1 immunoreactive hot spots of the same section as in (d). (f) Superposition of (d) and (e) shows that GluR1 immunoreactive hot spots are associated, but not in perfect register, with the ribbons. (g) Cone pedicle immunolabeled for bassoon. (h) Same pedicle, immunolabeled for GluR5. (i) Superposition of (g) and (h) shows that GluR5 immunoreactive hot spots are found in between the ribbons. (j) and (k) Section through a cone pedicle that was double labeled for GluR1 ((j), red) and GluR5 ((k), green). (l) Superposition of (j) and (k) shows that GluR1 and GluR5 immunoreactive puncta are expressed at different synaptic contacts. Scale bar = 5 μm.

and cat retina (Qin, P. and Pourcho, R. G., 1999; Hack, I. *et al.*, 2001), however, the corresponding type of bipolar cell has not yet been identified.

The kainate receptor subunit GluR5 has also been observed in flat contacts and has not been found in horizontal cell processes. In retinas double labeled for the ribbon marker bassoon and for GluR5, the GluR5 hot spots are always displaced from the ribbons, suggesting a NTA position (Figures 7(g)–7(h)). When cone pedicles were double labeled for the AMPA receptor subunit GluR1 and the kainate receptor subunit GluR5 (Figures 7(j)–7(l)), the labeled hot spots did not coincide (Haverkamp, S. *et al.*, 2001). This suggests that they are expressed by two different types of OFF-cone bipolar cells. In retinas of primates, rodents, and ground squirrels there was a significant reduction of GluR5 hot spots at S-cone pedicles in comparison to M/L- and L-cone pedicles (Haverkamp, S. *et al.*, 2001; Li, W. and DeVries, H., 2004; Haverkamp, S. *et al.*, 2005). The OFF-cone bipolar cell expressing GluR5 makes, therefore, only sparse connections with S-cones. The kainate receptor subunit KA-2 has also been observed at bipolar cell flat contacts and not in horizontal cell processes (Brandstätter, J. H. *et al.*, 1997).

The GluR subunits GluR2, GluR2/3, GluR4, and GluR6/7 have also been localized to flat contacts of bipolar cells at the cone pedicle base, however, these subunits also decorated the processes of horizontal cells (Morigiwa, K. and Vardi, N., 1999). NMDA receptor subunits have not been observed at the flat contacts (Fletcher, E. L. *et al.*, 2000).

In conclusion: OFF-cone bipolar cells express at their flat contacts with cone pedicles the AMPA receptor subunits GluR1, GluR2, GluR2/3, and GluR4, they also express the kainate receptor subunits GluR5, GluR6/7, and KA-2. Therefore, different OFF-cone bipolar cell types can be connected to cone pedicles through AMPA receptors, or through kainate receptors. Further diversity is to be expected because AMPA and kainate receptors are composed of four subunits each, and different subunits can be combined to form the tetrameric receptor complex.

1.12.4.4 Horizontal Cell Glutamate Receptors

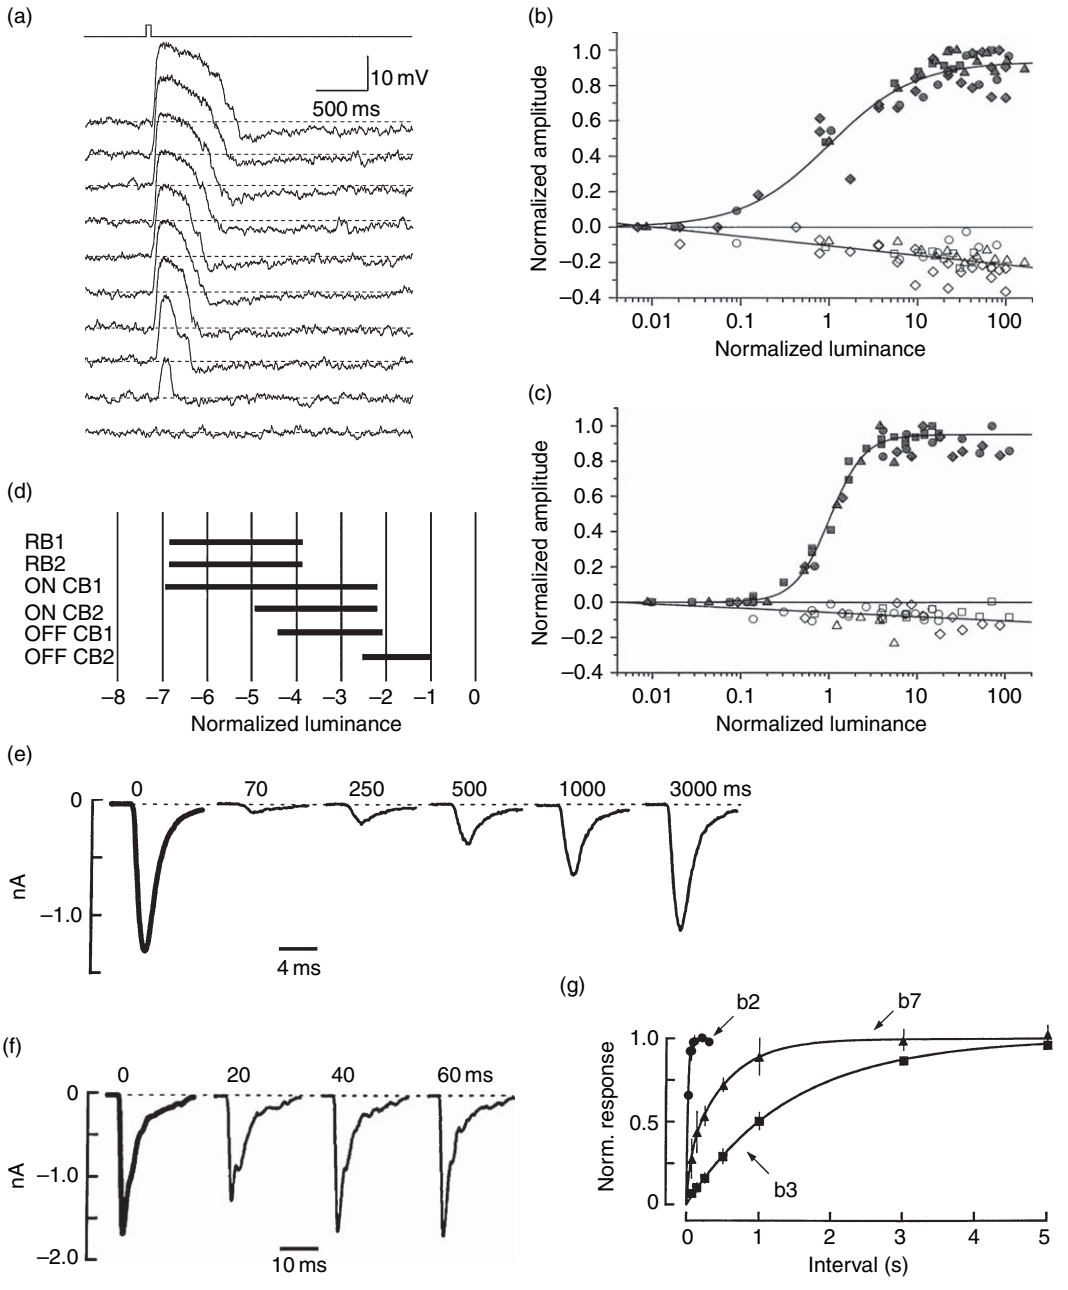
Horizontal cell dendrites of the primate retina express GluR hot spots at two postsynaptic locations: at the invaginating processes opposed to the presynaptic ribbons and at desmosomelike junctions between horizontal cell dendrites underneath the cone pedicle (Haverkamp, S. *et al.*, 2000). GluR2/3 and GluR4 clusters are found at the invaginating processes and at the desmosomelike junctions of all cone pedicles and these AMPA receptor subunits appear to constitute the dominant GluR expressed by horizontal cells (Figures 7(a)–7(c)). However, at M/L-cones pedicles horizontal cell dendrites also express the kainate receptor subunit GluR6/7. Since expression of GluR6/7 by horizontal cells was not observed at S-cone pedicles, the preferred target of H2 horizontal cells, it appears that only H1 horizontal cells express the GluR6/7 subunit (Haverkamp, S. *et al.*, 2001). The two horizontal types of the primate retina, therefore, not only have different shapes and cone contacts, but they express also different GluRs: H1 cells receive signals from cones through AMPA (GluR2/3, GluR4) and kainate (GluR6/7) receptors, H2 cells only through AMPA (GluR2/3, GluR4) receptors. Examination of GluR currents in horizontal cells from cultures human retina using whole-cell recordings showed that horizontal cells possess both AMPA and kainate receptors (Shen, W. *et al.*, 2004). Unfortunately the cells were not classified into H1 and H2 horizontal cells.

1.12.5 Light-Evoked Responses of Bipolar Cells

1.12.5.1 Temporal Transfer Characteristics

In the retinas of cold-blooded animals, especially the dogfish and the tiger salamander, the responses of bipolar cells to light have been studied extensively, contributing important results on the polarity (ON/OFF) and the time course (sustained/transient) of their responses, the currents involved, and the receptive field organization (Werblin, F. S., 1973; Kaneko, A. and Shimazaki, H., 1976; Saito, T. *et al.*, 1981; Saito, T. and Kujiraoka, T., 1982; Saito, T. *et al.*, 1985; Lasansky, A., 1992, Wu, S. M. *et al.*, 2000). Early recordings from intact mammalian retinas confirmed the ON/OFF dichotomy of cone bipolar cells (Nelson, R. *et al.*, 1981; Nelson, R. and Kolb, H., 1983) and showed that RB cells are ON-bipolar cells (Dacheux, R. F. and Raviola, E., 1986). Later, in patch clamp recordings from dissociated bipolar cells it was shown that RB cells express the metabotropic L-AP4 sensitive GluR, while cone bipolar cells express both ionotropic and metabotropic GluRs (Yamashita, M. and Wässle, H., 1991; de la Villa, P.

et al., 1995). Recordings from bipolar cells in rat retinal slices, together with a morphological identification of the cells and the application of glutamate agonists demonstrated that types 1, 2, 3, and 4 are OFF bipolar cells, while types 5, 6, 7, 8, 9, and RB cells are ON bipolar cells (Euler, T. *et al.*, 1996; Hartveit, E., 1996; 1997). In the retina of the ground squirrel dual recordings from synaptically connected cone pedicles and different bipolar cell types were performed (DeVries, S. H. and Schwartz, E. A., 1999; DeVries, S. H., 2000). The signal transfer between cones and OFF-cone bipolar cells was based on two different types of ionotropic GluRs: bipolar cell types b3 and b7 expressed kainate receptors, type b2 AMPA receptors. The three cell types showed substantial differences in their temporal properties as measured by their recovery from desensitization (Figures 8(e)–8(g)). Type b2 cells showed fast, b7



cells medium, and b3 cells show recovery. The rapidly recovering b2 cell AMPA receptors are well suited to signal transient components in the cone light response, whereas the slowly recovering b3 cell kainate receptors attenuate the transient components and consequently emphasize the steady (sustained) components. Further studies of the cone pedicle architecture of the retina of the ground squirrel showed that the b2 cells made TA contacts (DeVries, S. H. *et al.*, 2006) and consequently respond fast and transiently. The b3 and b7 cells made basal contacts further away from the triads (NTA) and glutamate released at the ribbons had a long way of diffusion, which resulted in smoothed and sustained responses of b3 and b7 cells. This shows that the cone to OFF bipolar synapse is an important locus in temporal processing. So far it has not yet been shown for the mammalian retina that the cone to ON bipolar synapse is also involved in temporal processing. However, Awatramani G. B. and Slaughter M. M. (2000) have shown that the cone to ON-bipolar synapse of the tiger salamander retina transduces either a sustained or a transient response.

In the rodent retina a specific expression of voltage-dependent sodium (Na^+) and K^+ channels was observed in retinal bipolar cells (Klumpp, D. J. *et al.*, 1995a; 1995b; Pan, Z. H. and Hu, H. J., 2000; Ma, Y. P. *et al.*, 2005). The presence of Na^+ channels in a subgroup of ON-cone bipolar cells accelerated their response kinetics and amplitudes. The results show that the expression of different GluRs at the cone pedicle base and the intrinsic, voltage-dependent Na^+- and K^+-channel shape the temporal transfer characteristic of the different bipolar cell types. Further temporal specificity is contributed by the expression of different voltage-dependent Ca^{2+}-channels at the bipolar cell output synapses (Protti, D. A. and Llano, I., 1998; Pan, Z. H., 2000; Protti, D. A. *et al.*, 2000). The transmitter release at the bipolar cells axon terminal is also controlled by the expression of hyperpolarization-activated and cyclic nucleotide-gated (HCN) channels. Different classes of bipolar cells have a different inventory of HCN channels, which are densely clustered at their axon terminals (Müller, F. *et al.*, 2003; Ivanova, E. and Müller, F., 2006).

1.12.5.2 Spatial Transfer Characteristics

Midget bipolar cells of the primate retina contact, up to an eccentricity of ~10 mm, as a rule, one cone pedicle, diffuse bipolar cells between five and 10 cone pedicles. Dacey D. M. *et al.* (2000) measured the receptive field profiles of midget and diffuse bipolar cells at ~10 mm eccentricity and observed for both cell types an antagonistic center/surround organization: ON center/OFF surround and OFF center/ON surround. The mean center diameter of midget bipolar cells was 42 µm, which would encompass ~5–10 cones. The mean center diameter of diffuse bipolar cells was 92 µm, which would suggest input from 20 to 30 cones. The basis for the apparently large receptive field center sizes is electrical coupling of neighboring cone pedicles (Raviola, E. and

Figure 8 Electrophysiological recordings from bipolar cells of the mouse (a–d) and of the retina of the ground squirrel (e–g). (a) Whole cell recordings of the light-evoked depolarizations of a rod bipolar (RB) cell in a slice preparation of the mouse retina (light stimulus 50 ms, Vrest = 43 m V, intensity stepwise increased from 0 cd m^{-2} at the bottom to 43.5 cd m^{-2} at the top trace). The light-evoked potential is a depolarization followed by a hyperpolarization. (b) Sensitivity curves of four intact RB cells sowing the normalized amplitude (V/V_{max}) of the light-evoked voltage responses as a function of the normalized (I/I_{50}) stimulus intensity (logarithmic axis). Each symbol represents one cell (filled symbols depolarization, open symbols hyperpolarization). (c) Sensitivity curves of four axotomized RB cells. Comparison with (b) shows that they are steeper. (d) Dynamic range of the light responses of two RB, two ON-cone bipolar, and two OFF diffuse bipolar cells of the mouse retina. The abscissa shows the normalized stimulus intensity (logarithmic units). The horizontal bars indicate for the light intensity range from threshold (5%) to saturation (95% of the maximum response) of the light-evoked excitatory currents. Adapted from Wu, S. M., Gao, F., and Pang, J. J. 2004. Synaptic circuitry mediating light-evoked signals in dark-adapted mouse retina. Vision Res. 44, 3277–3288. (e–g) Whole-cell currents elicited in three types of OFF-bipolar cells (b2, b3, b7) of the retina of the ground squirrel by the application of brief pulses (15 ms) of glutamate (2 mM) separated by variable intervals. (e) The average first response (thick line) and subsequent responses (thin lines) are shown for a b3 cell. The interpulse interval is given above each trace. (f) Recordings of glutamate responses of a b2 cell. The recovery from desensitization of this b2 cell is much faster than that of the b3 cell shown in (e). (g) Normalized peak response is plotted against interpulse interval (b2, $n = 5$; b3, $n = 9$; b7, $n = 5$). Type b2 bipolar cells show the fastest recovery ($\tau = 18$ ms), followed by b7 and b3 cells. Type b2 cells signal through α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, b7 and b3 cells through two different kainate receptors. Adapted from DeVries, S. H. 2000. Bipolar cells use kainate and AMPA receptors to filter visual information into separate channels. Neuron 28, 847–856.

Gilula, N. B., 1973; Tsukamoto, Y. *et al.*, 1992; Hornstein, E. P. *et al.*, 2004; 2005). It is also possible, that neighboring bipolar cells are electrically coupled (Feigenspan, A. *et al.*, 2004; Han, Y. and Massey, S. C., 2005).

The mean diameter of the antagonistic surround of midget and diffuse bipolar cells was 467 µm and 743 µm, respectively. For midget bipolar cells, the surrounds are about the same as the receptive field diameters of macaque H1 horizontal cells (Dacey, D. M., 2000). The diffuse bipolar cell surrounds are consistently larger, suggesting in addition to the horizontal cell input an input at their axon terminal system from a wide field amacrine cell type.

1.12.6 Intensity-Response Function

RB cells have the lowest response threshold for light stimuli amongst mammalian bipolar cells (Figures 8(a)–8(d)). The mean threshold (defined as 5% of the maximum response) of mouse RB cells is 0.1 Rh^* rod^{-1} s^{-1} and their dynamic range is ~3.3 log units (Wu, S. M. *et al.*, 2004). This is more than 1 log unit wider than the rod photocurrent (Field, G. D. and Rieke, F., 2002). The light-evoked response of RB cells increases monotomically (Figure 8(a)) and follows a Hill function (Figure 8(b)) with a Hill coefficient of 1.07 ± 0.19 (Euler, T. and Masland, R. H., 2000) and 1.15 ± 0.11 (Berntson, A. and Taylor, W. R., 2000). Euler T. and Masland R. H. (2000) measured also the intensity–response function of RB cells which had lost their axons (axotomized). The dynamic range of the axotomized RB cells was reduced by more than 1 log unit and the Hill curve was much steeper (Hill coefficient 2.39 ± 0.84; Figure 8(c)). A comparable reduction of the dynamic range of RB cells was also observed when the cells were superfused with GABA antagonists. Both results show, that GABAergic inhibition at RB axon terminals can modulate the intensity-response function of RB cells. This conclusion is also supported by recent measurements of bipolar cells in $GABA_C$ receptor knockout mice (McCall, M. A. *et al.*, 2002).

The thresholds for light stimuli of ON-cone bipolar cells of the mouse retina are generally higher than those for RB cells (Wu, S. M. *et al.*, 2004). Different types of ON-cone bipolar cells exhibit different thresholds and dynamic ranges, and thus cover only a small range of light intensities (~2 log units). The full range of intensities transferred to the inner retina is therefore encoded by different bipolar cells types (Figure 8(d)).

1.12.7 Synaptic Contacts of Bipolar Cells in the Inner Plexiform Layer

The axons of bipolar cells terminate in the IPL in lobular swellings (Figure 9). Some bipolar cell types, such as DB3 and DB6 of the primate retina and type 7

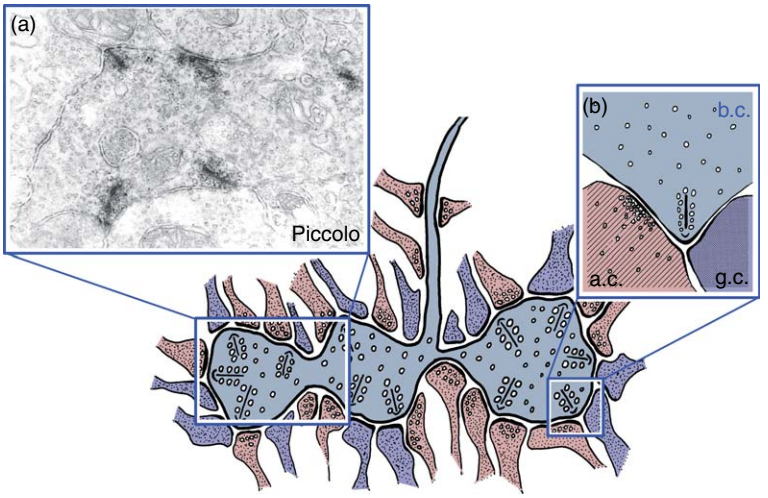


Figure 9 Synaptic output of bipolar cells in the inner plexiform layer. Schematic diagram of the axon terminal of a cone bipolar cell. It contains many presynaptic ribbons that are flanked by synaptic vesicles. (a) Electron micrograph of the axon terminal of a rod bipolar cell. Kindly provided by O. Dick. The five ribbons are marked by their expression of the ribbon associated protein piccolo. (b) Magnified view of a cone bipolar cell ribbon synapse (dyade). The presynaptic bipolar cell (b.c.) releases glutamate and the two postsynaptic partners (a.c., amacrine cell; g.c., ganglion cell) express two different sets of glutamate receptors. The amacrine cell in turn makes a synapse back onto the bipolar cell terminal (reciprocal synapse).

of the mouse retina keep their axon terminals within a narrow stratum (Figure 6; Chan, T. L. *et al.*, 2001; Jusuf, P. R. *et al.*, 2004; Lin, B. *et al.*, 2005). Hence their output will be restricted to the amacrine and ganglion cell dendrites they meet within that stratum. Other bipolar cells such as type 4 and type 6 of the mouse retina occupy with their axon terminals the complete OFF- or ON-sublamina, respectively (Ghosh, K. K. *et al.*, 2004). They are possible engaged in contacts with a wider variety of postsynaptic neurons. Midget bipolar cells of the primate retina represent a special case, because their axon terminals precisely match in width and depth the dendritic tops of midget ganglion cells, and they together form a densely interconnected glomerulus that can only be resolved by EM (Kolb, H. and Dekorver, L., 1991; Calkins, D. J. *et al.*, 1994; Jusuf, P. R. *et al.*, 2006). The axon terminals of neighboring bipolar cells of a given type usually tile the retina without much overlap in horizontal direction (RB cells: Young, H. M. and Vaney, D. I., 1991; midget cells: Wässle, H. *et al.*, 1994; calbindin bipolar cells of the rabbit: Massey S. C. and Mills S. L., 1996). Because of this basically onefold coverage the density of a given bipolar cell type is inversely proportional to the area occupied by the axon terminals (Figure 6(e)).

Bipolar cell axon terminals provide synaptic output through multiple ribbon synapses. The number of ribbon synapses made by midget bipolar cells of the macaque monkey retina ranged from nine to 48 (mean $\pm$ standard deviation 26.5 ± 9.3; Jusuf, P. R. *et al.*, 2006). An earlier report that this number differed between midget bipolar cells contacting M- or L-cones (Calkins, D. J. *et al.*, 1994) was not confirmed by Jusuf P. R. *et al.* (2006). The number of ribbon synapses made by RB cells of the rabbit retina was up to 30 compared to only 15 in the rat retina (Strettoi, E. *et al.*, 1990; Chun, M. H. *et al.*, 1993), which reflects the smaller size of RB axon terminals in rats (Figure 9(a)). The fine structure of the bipolar cell output synapses in the IPL was first described from EM by Missotten L. (1965). He identified the presynaptic ribbon surrounded by vesicles and the two postsynaptic elements. Dowling J. E. and Boycott B. B. (1966) named this synaptic arrangement a dyad. They recognized that one of the postsynaptic partners at cone bipolar cell dyads was usually a ganglion cell dendrite, while the other one was an amacrine cell process (Figure 9(b)). The amacrine cell process often made within about 0.5–1.0 µm of the dyad a conventional synapse back onto the bipolar cell axon terminal. This arrangement appears to be a reciprocal synapse and because most amacrine cells are inhibitory it is the structural correlate of negative feedback at the dyad. Bipolar cell axons receive in addition to reciprocal synapses also input from amacrine cells not related to the dyads (Sterling, P. and Lampson, L. A., 1986). In the case of RB cell dyads both postsynaptic partners are amacrine cells (AI and AII; Famiglietti, E. V. and Kolb, H., 1975; Kolb, H. and Famiglietti, E. V., 1976) and AI cells provide the reciprocal synapses (see Mammalian Rod Pathways).

The molecular composition of the presynaptic ribbon of bipolar cell dyads is similar to that of photoreceptor ribbons. RIBEYE, CtBP2, Kif3a, and Piccolo have all been localized to the bipolar cell ribbons (Muresan, V. *et al.*, 1999; Schmitz, F. *et al.*, 2000; tom Dieck, S. *et al.*, 2005; Deguchi-Tawarada, M. *et al.*, 2006; Jusuf, P. R. *et al.*, 2006) and this suggests that the mechanisms of glutamate release is also comparable to the photoreceptors synapses. Mb1-bipolar cells of the goldfish retina have a large, round axon terminal, and vesicle fusion, exocytosis, and endocytosis have been studied on this model system in great detail (von Gersdorff, H., 2001; Berglund, K. *et al.*, 2002; Heidelberger, R. *et al.*, 2002; Zenisek, D. *et al.*, 2000; Lagnado, L., 2003; Zenisek, D. *et al.*, 2003; Singer, J. H. *et al.*, 2004; Zenisek, D. *et al.*, 2004). The voltage signals that control neurotransmitter release from bipolar cells are graded with the intensity of the light stimulus and maintained according to the duration of the stimulus. These sustained signals stimulate a continuous cycle of vesicle exocytosis and endocytosis. The ribbon holds vesicles for exocytosis. The most direct evidence for this idea comes from the work of Zenisek D. *et al.* (2000) who used total internal reflection fluorescence microscopy (TIRF) to image individual vesicles in the synaptic terminal of Mb1-bipolar cells.

Glutamate release from bipolar cell terminals *a priori* depends upon the graded electrical response of the cell elicited by the light stimulus. However, it is also regulated by diverse feedback mechanisms acting at the dyad. (1) GABA or glycine released by the amacrine cells can feedback onto the bipolar cell terminal (Euler, T. and Masland, R. H., 2000; Shields, C. R. *et al.*, 2000; Matsui, K., *et al.*, 2001; Freed, M. A. *et al.*, 2003). (2) Bipolar cell terminals express mGluRs as autoreceptors that regulate voltage-dependent Ca^{2+}-channels (Awatramani, G. B. and Slaughter, M. M., 2001; Brandstätter, J. H. *et al.*, 1998; Palmer, M. J. *et al.*, 2003). (3) Bipolar cell axon

terminals express cannabinoid receptors, which regulate voltage-dependent K^+-channels (Fan, S. F. and Yazulla, S., 2005). (4) Synaptic vesicles release protons that inhibit Ca^{2+}-channels and thus inhibit locally the release (Hosoi, N. *et al.*, 2005).

1.12.8 Glutamate Receptors in the Inner Plexiform Layer

Bipolar cells release glutamate at their ribbon synapses (Tachibana, M., 1999) and the GluRs are clustered in the postsynaptic membranes adjacent to the ribbons. As a rule, only one member of the dyad expresses a given GluR subunit, which implies that the two postsynaptic partners express different GluRs (Hartveit, E. *et al.*, 1994; Qin, P. and Pourcho, R. G., 1996; Brandstätter, J. H. *et al.*, 1997; Qin, P. and Pourcho, R. G., 1999; Fletcher, E. L. *et al.*, 2000; Grünert, U. *et al.*, 2002). The postsynaptic clusters of GluRs appear as brightly immunofluorescent puncta when studied by light microscopy and their density and laminar distribution across the IPL differs for the different subunits (Figure 10).

1.12.8.1 α-Amino-3-Hydroxy-5-Methyl-4-Isoxazolepropionic Acid Receptor Subunits

The GluR1-immunoreactive puncta in the IPL have a stratified distribution and several bands of high and low expression can be recognized (Figure 10(a)). Some amacrine and ganglion cells are labeled extrasynaptically and GluR1 is probably expressed by a subset of these cell classes. GluR2/3-immunoreactive puncta occur at high density across the IPL with an increased density along the strata occupied by the dendrites of cholinergic amacrine cells (Figure 10(b)). The GluR4 subunit shows an even distribution of puncta across the OFF- and ON-sublamina of the IPL (Figure 10(c)). The GluR2/3 and the GluR4 subunits have been observed at the vast majority of bipolar cell ribbons in rabbit and primate retinas (Ghosh, K. K. *et al.*, 2001; Jusuf, P. R. *et al.*, 2006) which implies that at least one member of the dyad usually expresses an AMPA receptor. In the case of RB cells it has been shown that AII cells express the GluR2/3 and GluR4 subunits (Ghosh, K. K. *et al.*, 2001; Li, W. *et al.*, 2002). Physiological recordings from synaptically connected pairs of RB and AII cells have also shown

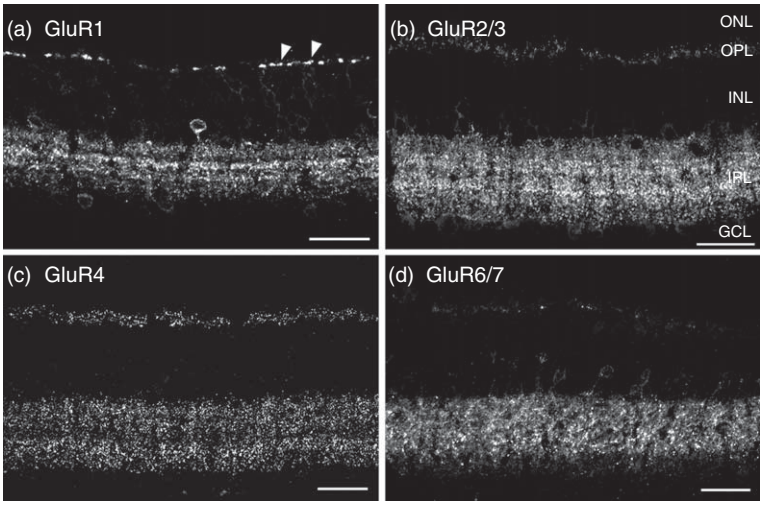

Figure 10 Expression of glutamate receptors (GluRs) in the inner plexiform layer (IPL) of the mouse retina. Confocal fluorescence micrographs of vertical sections that were immunolabeled for GluR subunits. (a) The GluR1 subunit is found extrasynaptically in bipolar, amacrine, and ganglion cells. The dashed line (arrowheads) in the outer plexiform layer (OPL) represents labeling of bipolar cell dendritic tips underneath cone pedicles. A punctate distribution representing synaptic clustering is found in the IPL. (b) The GluR 2/3 subunit shows punctate fluorescence in both the OPL and the IPL. (c) The GluR4 subunit is also found in synaptic hot spots both in the OPL and the IPL. The band of puncta in the OPL is rather wide in (b) and (c), suggesting that processes associated with rod spherules such as horizontal cell axon terminals are also labeled. (d) The kainate receptor subunit GluR 6/7 shows sparse label in the OPL, although many immunofluorescent puncta are present throughout the IPL. Scale bars = 25 μm. Adapted from Haverkamp, S. and Wässle, H. 2000. Immunocytochemical analysis of the mouse retina. J. Comp. Neurol. 424, 1–23.

that AMPA receptors mediate the signal transfer from RB to AII cells (Veruki, M. L. *et al.*, 2003; Singer, J. H. and Diamond, J. S., 2003).

1.12.8.2 Kainate Receptor Subunits

Immunoreactive puncta representing synaptic clusters of kainate receptor subunits KA2 and GluR6/7 have been found throughout the IPL (Figure 10(d); Qin, P. and Pourcho, R. G., 1996; Brandstätter, J. H. *et al.*, 1997; Qin, P. and Pourcho, R. G., 1999). Peng Y. W. *et al.* (1995) observed labeling of some amacrine and ganglion cells for GluR6/7, suggesting they both can express kainate receptors. Whole-cell recordings have shown that some amacrine cells express exclusively kainate receptors others express only AMPA receptors and many amacrine cells have a mixed population of GluRs (Dumitrescu, O. N. *et al.*, 2006). Kainate receptors were found to play only a minor role in generating the light-evoked synaptic currents of brisk sustained (X) type ganglion cells of the cat retina (Cohen, E. D., 2000). Synaptic clusters of the orphan receptor subunits $\delta 1/2$ have also been observed throughout the IPL (Brandstätter, J. H. *et al.*, 1997) postsynaptic to OFF-cone, ON-cone, and RB cells. However, in only one instance the postsynaptic partner was identified; the AI cell at RB cell terminals (Ghosh, K. K. *et al.*, 2001; Li, W. *et al.*, 2002). Unfortunately it is not yet known, which other GluR subunits, together with the $\delta 1/2$ subunits, constitute the GluR receptor channel of AI cells, however, kainate receptor subunits are the most probable candidates.

1.12.8.3 *N*-Methyl-D-Aspartate Receptor Subunits

Synaptic clusters of NMDA receptor NR1 subunits, which are a necessary constituent of all NMDA receptors, have been observed in the IPL, extending from the border of the amacrine cell layer to the innermost part of the IPL. There is a marked reduction of NMDA receptor clusters in the inner part of the IPL, where RB cells terminate (Fletcher, E. L. *et al.*, 2000; Kalloniatis, M. *et al.*, 2004), and signaling through NMDA receptors appears to have only a minor role in the signal transfer from RB cells to AI/AII cells (Boos, R. *et al.*, 1993; Singer, J. H. and Diamond, J. S., 2003; Veruki, M. L. *et al.*, 2003). The two subunits NR2A and NR2B have also a punctate distribution in the IPL; however, the density of puncta differs for the two subunits. Approximately four bands of higher density can be discerned for the NR2A subunit, in contrast to a prominent band in the center of the IPL in the case of the NR2B subunit. Only ~30% of the NR2A and NR2B clusters were found to coincide. These results suggest that there are at least three different types of postsynaptic NMDA receptor clusters in the IPL: those containing NR1/NR2A, NR1/NR2B, and only a small number composed of NR1/NR2A/NR2B.

NMDA receptors play an important role in the transfer of light signals from cone bipolar cells onto ganglion cells. This was first demonstrated in the retina of cold blooded animals (Mittman, S. *et al.*, 1990; Diamond, J. S. and Copenhagen, D. R., 1993; 1995; Matsui, K. *et al.*, 1998; Higgs, M. H. and Lukasiewicz, P. D., 1999). However, although light evoked, NMDA receptor mediated, postsynaptic currents were measured in these studies, spontaneous miniature postsynaptic currents (sEPSCs) lacked a NMDA receptor-mediated component. Light-evoked excitatory synaptic currents of brisk sustained (X) ganglion cells of the cat retina showed also a significant contribution from NMDAR (Cohen, E. D., 2000). In rat RGCs electrically evoked EPSCs recorded from ganglion cells were also mediated by both AMPA and NMDA receptors (Chen, S. and Diamond, J. S., 2002); however, sEPSCs were mediated solely by AMPA receptors. This problem was recently solved by the application of postembedding immunelectron microscopy: AMPA and NMDA receptors are both aggregated on ganglion cell dendrites postsynaptic to the bipolar cell ribbon. However, AMPA receptors are immediately adjacent to the ribbon and the glutamate release site, while NMDA receptors are found perisynaptically at some distance from the ribbon (Zhang, J. and Diamond, J. S., 2005). They are only activated during multivesicular, light-activated glutamate release and do not detect the small amount of glutamate released by the fusion of a single vesicle (Singer, J. H. *et al.*, 2004).

1.12.8.4 Metabotropic Glutamate Receptors

Of the eight different mGluR subtypes known presently, all but mGluR3 have been shown to be expressed and distinctly localized in the rodent retina (Tagawa, Y. *et al.*, 1999). They are clustered at the bipolar cell output synapses and EM has shown that they can occupy a pre- and/or postsynaptic position (Brandstätter, J. H. *et al.*, 1996; Koulen, P. *et al.*, 1996). Usually only one member of the dyad expresses a

given mGluR. The distribution of mGluR clusters across the IPL is different. The subtype mGluR2 for instance is enriched in two narrow bands of the IPL which coincide with the bands of the dendrites of cholinergic amacrine cells (Koulen, P. *et al.*, 1996). Postsynaptic clusters expressing the subtype mGluR7are enriched in four broad horizontal bands and show a reduced density along the cholinergic bands (Brandstätter, J. H. *et al.*, 1998). The different mGluR subtypes are unlikely to be involved with the direct signal transfer from bipolar cells onto the postsynaptic amacrine and ganglion cells. They are supposed to be modulators and it has been shown that $GABA_C$ receptors of RB cells are regulated down by mGluR1/5 agonists (Euler, T. and Wässle, H., 1998).

1.12.8.5 Co-Stratification of Pre- and Postsynaptic Partners in the Inner Plexiform Layer

Bipolar axons terminate at distinct levels within the IPL, and different types of amacrine and ganglion cells also keep their processes at specific levels within the IPL, which leads to the prediction that they also are engaged in mututal synaptic contacts (Figures 11(a)–11(d); Masland, R. H., 2001; Roska, B. and Werblin, F., 2001; Jusuf, P. R. *et al.*, 2004; Wässle, H., 2004; Lin, B. *et al.*, 2005; Coombs, J. *et al.*, 2006; Kim, T. J. and Jeon, C. J., 2006). However, this simple rule has only been verified in a few instances. Midget bipolar cells of the primate retina – both ON- and OFF-midget – contact midget ganglion cells and their axon terminal together with the ganglion cell dendrites form a kind of glomerulus (Kolb, H. and Dekorver, L., 1991; Calkins, D. J. *et al.*, 1994; Jusuf, P. R. *et al.*, 2006). Midget ganglion cells of the primate retina show sustained light responses and this predicts that midget bipolar cells also have sustained light responses.

Parasol ganglion cells of the primate retina also occur as OFF- and ON-pairs and their dendrites stratify in sublamina 2 and sublamina 4, respectively (Watanabe, M. and Rodieck, R. W., 1989; Dacey, D. M. and Packer, O. S., 2003; Dacey, D. M., 2004). OFF-parasol cells receive their major, excitatory input from DB3 bipolar cells (Calkins, D. J., 1999; Jacoby, R. A. *et al.*, 2000), ON-parasol cells from DB4/DB5 bipolar cells (Marshak, D. W. *et al.*, 2002). The DB3

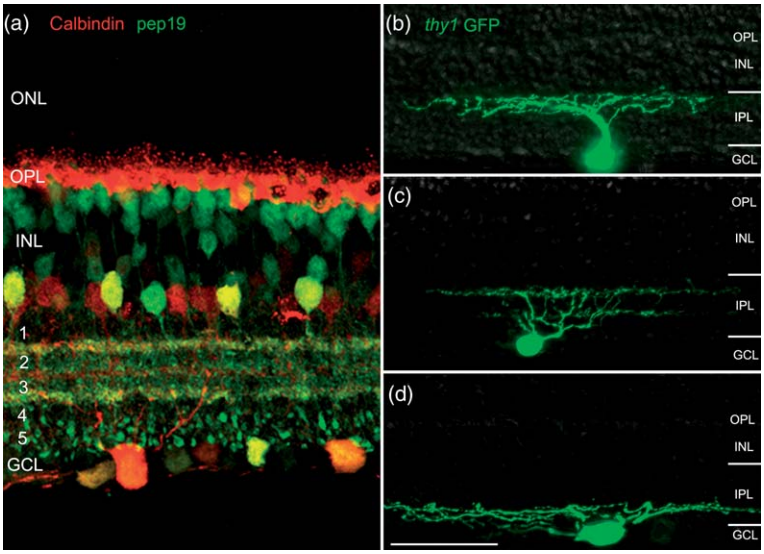

Figure 11 Stratification and functional subdivision of the inner plexiform layer (IPL). (a) Vertical section through a mouse retina that was double immunostained for calbindin (red) and for Pep 19 (green). Calbindin is expressed in horizontal, some amacrine, and some ganglion cells. Pep 19 labels rod bipolar (RB) cells, a subpopulation of cone bipolar, amacrine (among them the cholinergic amacrine cells) and ganglion cells. Their processes subdivide the IPL into distinct strata; among them are the OFF-(sublamina 1/2) and the ON-(sublamina 3/4) cholinergic strata. The axon terminals of RB cells terminate in stratum 4/5. Adapted from Haverkamp, S. and Wässle, H. 2000. Immunocytochemical analysis of the mouse retina. J. Comp. Neurol. 424, 1–23. (b) Vertical section through a transgenic mouse retina where ganglion cells express green fluorescent protein under the control of the thy1 promotor (Feng, G. *et al.*, 2000). This putative OFF (C2 type) ganglion cell stratifies in the outer IPL. (c) This bistratified (putative direction selective (DS)) cell stratifies at the same level as the cholinergic amacrine cells. This putative ON (A-type) ganglion cell stratifies in the inner IPL. Scale bar = 50 μm.

bipolar cell of the primate and the b2 cell of the ground squirrel are probably homologous types (DeVries, S. H., 2000). Since b2 cells receive their light signals through AMPA receptors, they have a high temporal transfer rate. This would be in accordance with the high flicker fusion frequency of parasol cells (Lee, B. B. *et al.*, 1988). Lin B. and colleagues (2005) studied the costratification of type 7 bipolar cell axon terminals and ganglion cell dendrites of the mouse retina. One monostratified ganglion cell and one bistratified cell tightly cofasciculate with the axon terminals of type 7 bipolar cells.

The small bistratified ganglion cells of the primate retina are the blue ON/yellow OFF ganglion cells (Dacey, D. M. and Lee, B. B., 1994). They have their inner dendritic tier in stratum 5 and their outer dendritic tier in stratum 1 of the IPL. The inner tier coincides with the axon terminal of blue-cone bipolar cells (BB in Figure 2), which provide the S-ON input. The outer tier collects synapses from DB2/DB3 bipolar cells and they provide the M- and L-OFF input (Calkins, D. J. *et al.*, 1998; Calkins, D. J., 2001). A further bistratified ganglion cell of the mammalian retina is the ON/OFF direction-selective (DS) ganglion cell (Amthor, F. R. *et al.*, 1989; Figure 11(c)). The inner and outer tier of its dendritic tree coincides with the level of stratification of ON- and OFF-cholinergic amacrine (Famiglietti, E. V., 1992) cells. Mouse cone bipolar cell axon terminals have been studied with respect to their costratification with the cholinergic strata (Ghosh, K. K. *et al.*, 2004; Pignatelli, V. and Strettoi, E., 2004), however, none of the nine types precisely coincided with the dendrites of cholinergic amacrine cells. In the rabbit retina it was shown that DS ganglion cells receive direct input from bipolar cells, however, the majority of their synaptic input is from amacrine cells (Dacheux *et al.*, 2003).Brown S. and Masland R. (1999) identified an ON-cone bipolar cell of the rabbit retina by its immunoreactivity for the carbohydrate epitope CD15 and demonstrated that CD15-positive bipolar cells axon terminals stratify within and slightly more distally of the ON-cholinergic band. In addition, they follow the pattern of the ON-cholinergic dendrites, and are, therefore, good candidates for providing synaptic input to the DS circuitry.

1.12.9 Conclusions

At least 10 different types of bipolar cells transfer the visual signals from the outer to the inner retina. RB cells are exclusively connected to rod spherules and they are involved with the transfer of scotopic signals. The major distinguishing anatomical feature of the different types of cone bipolar cells is the level of stratification of their axons in the IPL, where they preferentially contact those ganglion and amacrine cells which have their dendrites at the same level within the IPL. Some of the bipolar cells select certain types of cones, such as the midget bipolar cells of the primate retina or the blue-cone bipolar cells of most mammals and they transfer a chromatic signal into the IPL. However, most bipolar cells contact all cones, usually five to 10, within their dendritic field and they differ in their intrinsic properties. The major subdivision is into ON- and OFF-bipolar cells, and this is based on two different types of GluRs expressed at their dendrites: ionotropic GluRs in OFF-bipolars and mGluR6 in ON-bipolars. OFF-bipolar cells can be further subdivided according to the specific expression of AMPA or kainate receptors. The physiological consequences of this molecular diversity are different temporal resolution and possibly different threshold sensitivity. The axon terminals of bipolar cells in the IPL release glutamate at their output synapses. The release depends upon the intrinsic membrane properties of bipolar cells (HCN, K^+-, Na^+-, and Ca^{2+}-channels). It can also be modulated by the mGluR autoreceptors and possibly by other receptors, such as dopamine or cannabinoid receptors. Feedback from amacrine cells has been shown to regulate the bipolar cell intensity/response function. The postsynaptic partners of bipolar cells, amacrine, and ganglion cells also express different sets of GluRs, including NMDA receptors and mGluRs. How this molecular diversity is translated into the transfer of the light signal through the retina remains a challenging question.

1.13.1 Basic Circuit

The horizontal cell receives synaptic input signals exclusively from photoreceptors and transmits back to them an inverted signal. This signal, called negative feedback, modulates the photoreceptors' release of neurotransmitter. The feedback signal is generated by a specialized synapse between the tip of the horizontal cell dendrite and the photoreceptor terminal. The exact nature of the synapse is unknown but there is convincing evidence for feedback mediated by gamma-aminobutyric acid (GABA), electrical conduction (ephaptic), and/or pH. There is also evidence for a GABAergic feedforward connection to bipolar cells. The horizontal cell's contribution to vision is important in two contexts:

1. its contribution to the ganglion cell receptive field and
2. its hypothesized noise-reducing function in the outer plexiform layer (OPL).

1.13.2 Types of Horizontal Cells

1.13.2.1 Morphology in Cat and Rabbit

Most vertebrates have at least two horizontal cell types (Figure 1). In cat and rabbit, two types process cone signals. One is larger (~250 μm) with a sparser dendritic tree, called type A or simply HA, and the other is smaller (~100 μm), with a more bushy dendritic tree, called type B or HB (Boycott, B. B. *et al.*, 1978). In addition, the HB has an axon ending in a large terminal, sometimes called HBAT (HB axon terminal), looking like an extensive but sparse dendritic tree, which receives synaptic connections from rods. The axon proceeds about 500 μm from the soma and is narrow (~0.3 μm) so the axon terminal's rod-driven signal is thought to be functionally independent from the soma's cone-driven signal, almost as if the axon terminal were a separate neuron (Golard, A. *et al.*, 1992). Most other mammals have two horizontal cell types very similar to those in cat and rabbit.

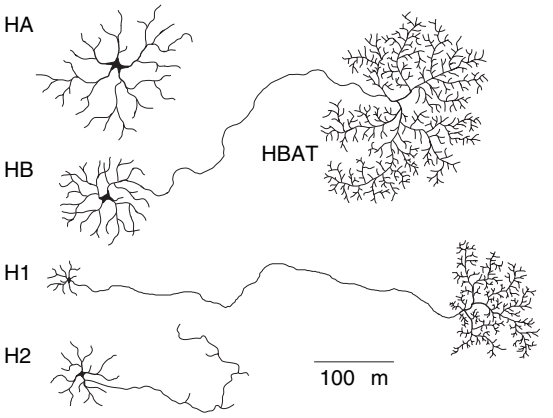

Figure 1 Two types of horizontal cell exist in most mammals. HA is larger, more sparse, with no axon. HB is smaller, and more bushy, with axon. In cat/rabbit, HA connects to ~200 cones, HB to ~100. The HB axon terminal (HBAT) connects to ~2000 rods, and is tethered to its parent HB by a ~400 μm axon, thought to be long and thin enough to maintain rod signal isolation. Two corresponding types H1, H2 exist in primate. They are proportionately smaller and connect to about tenfold fewer cones. The H2 has a sparse axon, which connects exclusively to S cones. An additional type, H3 (not illustrated) is similar to H1 but is 30% larger and more asymmetrical. Adapted from Boycott B. B. *et al.* (1978) and Kolb H. *et al.* (1992).

1.13.2.2 Types in Primate and Other Species

In primate, three anatomical types have been classified, types H1, H2, and H3, where H1 is smaller with a rod connecting axon, analogous to HB in cat (Kolb, H. *et al.*, 1992), and H2 is larger, analogous to HA in cat. Primate type H3 is similar to H1 except that H3 is larger, contacting 30% more cones with an asymmetrical dendritic field. Rat and mouse have only one horizontal cell type, analogous to the axon-bearing type HB in cat/rabbit, but this type appears to possess properties of both HA and HB (Peichl, L. and Gonzalez-Soriano, J., 1994; He, S. *et al.*, 2000). Other vertebrates (turtle, birds, and fishes) have several axonless horizontal cell types, some of which contact cone types seemingly indiscriminately, and others that make specific cone connections (Perlman, I. *et al.*, 2004).

1.13.2.3 Synaptic Inputs

Horizontal cell dendrites branch in the OPL just below the photoreceptor terminals and emanate very fine dendritic tips that contact the photoreceptors,

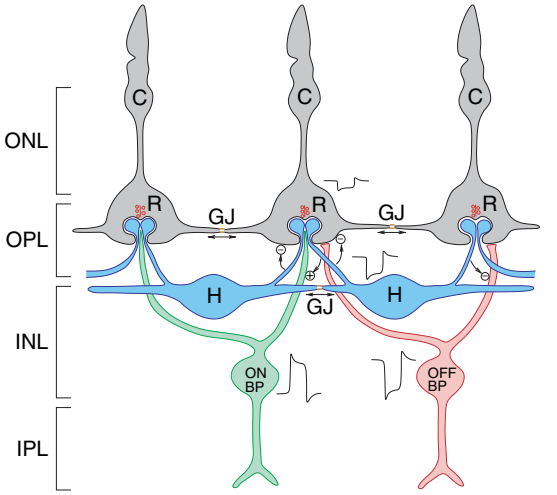

Figure 2 Schematic diagram of the outer retina showing the horizontal cell circuit. An array of cones (C) electrically coupled by gap junctions (GJ), provides input from ribbon synapse (R) to horizontal cells (H) and bipolar cells (ON BP, OFF BP). The triad is the association in the cone terminal between the ribbon and the dendritic processes from two horizontal cells and one ON bipolar cell. Horizontal cells exist in two or more types (not illustrated) and each type is electrically coupled by gap junctions (GJ). Response of cone to a flash of light is a small hyperpolarization, response of horizontal cell is a moderate hyperpolarization, response of OFF bipolar cell is a larger hyperpolarization, and response of ON bipolar cell (BP) is a larger depolarization. Feedback from horizontal cells to cones and feedforward to OFF bipolar cell is negative (arrow (−)), generating antagonistic surround. Feedforward from horizontal cells to ON bipolar cell is positive (arrow (+)), also generating an antagonistic surround in the ON bipolar because the bipolar's postsynaptic second messenger cascade inverts the signal it receives from cones. ONL, outer nuclear layer comprising photoreceptor (rod and cone) somas; OPL, outer plexiform layer where photoreceptors make synaptic connections to horizontal cells and bipolar cells; INL, inner nuclear layer comprising horizontal cell, bipolar cell, and amacrine cell somas; IPL, inner nuclear layer where bipolar cells and amacrine cells interconnect with ganglion cells. Diagram is not drawn to scale; elements of the triad feedback synapse are drawn larger in proportion to the neurons, and horizontal cells make synaptic connections with 100–200 cones.

where synaptic connections are made at a specialized synapse called a triad. This synapse, not fully understood, consists of an invagination formed in the photoreceptor membrane that contains dendritic tips of two horizontal cells and one or more bipolar cells (Figure 2). The horizontal cell processes are situated on either side of the presynaptic ribbon, which is a structure in the photoreceptor terminal involved in storage and release of vesicles (Parsons, T. D. and

Sterling, P., 2003). The synaptic output from photoreceptors is made at the ribbon synapse that releases vesicles containing the neurotransmitter glutamate. Postsynaptic glutamate receptors are located on the dendritic tips of horizontal cells and bipolar cells. The postsynaptic receptor on the horizontal cell is of the AMPA subtype (Morigiwa, K. and Vardi, N., 1999; Haverkamp, S. *et al.*, 2000; Pan, F. and Massey, S. C., 2007).

1.13.2.4 Topology and Connectivity

Horizontal cells exist in sufficient density that their dendrites are highly overlapped. HA and HB have a coverage factor of ~4 so each cone can potentially receive contacts from eight horizontal cells (Wassle, H. *et al.*, 1978b). Horizontal cells of most mammalian species, for example, the HA and HB in cat, receive connections from nearly all cones in their dendritic field (Kolb, H., 1977; Wassle, H. *et al.*, 1978a). The H1 of primate contacts most of the cones in its dendritic field, but mostly avoids S cones, and is analogous to HB with an axon collecting from rods. The H2 dendritic tree collects from all cone types and its axon collects specifically from S cones, and the H3 avoids S cones (Ahnelt, P. and Kolb, H., 1994). Therefore, horizontal cells cannot be the locus for color opponency in mammals (Dacey, D. M., 1996; Diller, L. *et al.*, 2004). In all vertebrates one horizontal cell type collects signals from rods; in mammals, this role is filled by the HBAT (see Section 1.13.3.8). Turtle, birds, and fishes have one luminosity type, one rod type, and two or more color-opponent types (see Chapter Vision in Birds).

1.13.2.5 Coupling

Most horizontal cells make connections only to their neighbors of the same type (homotypic) through gap junctions, which are electrical connections directly between the cytoplasm of one neuron and the next (Kolb, H., 1977). This electrical coupling broadens the receptive field and reduces noise. Type HA/H2 has strong coupling; type HB/H1 and its axon terminal have independent but weaker coupling. In most species, cones are also electrically coupled and are also interconnected to rods (Kolb, H., 1977; Smith, R. G. *et al.*, 1986; Hornstein, E. P. *et al.*, 2005). Coupling in horizontal cells and cones is modulated by light through dopamine released in the inner retina (DeVries, S. H. and Schwartz, E. A., 1989; Umino, O. *et al.*, 1991; Hampson, E. C. *et al.*, 1994; Baldridge, W. H. *et al.*, 1998; Xin, D. and Bloomfield, S. A., 1999; He, S. *et al.*, 2000; Witkovsky, P., 2004). The gap junctions between HAs are Cx50 type and between HBs the Cx57 type (O'Brien, J. J. *et al.*, 2006).

1.13.3 Functional Properties

1.13.3.1 Basic Light Response

Horizontal cells hyperpolarize to light, similar to photoreceptors, except that they have a greater response gain and adaptation (Wu, S. M., 1992). The HB/H1 has a cone-driven response in its soma and a rod response in its axon terminal. In addition, since rods and cones are interconnected, a rod signal is evident in cones and all cone-driven horizontal cells (Nelson, R., 1977). In turtle, fishes, and birds, color-opponent axonless types receive chromatic input from specific cone types. Their responses to color are complex because cones receive specific chromatic feedback from more than one horizontal cell type (Kamermans, M. *et al.*, 1991).

1.13.3.2 Response Properties

The light response of HA is fast, containing frequencies up to 100 Hz. The light response of HB is slower, containing frequencies up to 60 Hz. The receptive field of the HBAT is large and slowest at 30 Hz (Foerster, M. H. *et al.*, 1977). At high light intensities and contrasts, the light response may include a transient peak ($\tau \sim 50$–100 ms), derived from adaptation in the circuit but also from intrinsic properties. The biophysical properties of horizontal cells include several types of voltage-gated ion channel that amplify and shape its light response (Perlman, I. *et al.*, 1993; Aoyama, T. *et al.*, 2000), calcium-induced calcium release (Solessio, E. and Lasater, E. M., 2002), GABA release by vesicles and transporters (Schwartz, E. A., 2002; Hirano, A. A. *et al.*, 2005), and GABA autoreceptors, which are thought to amplify and lengthen its light response (Kamermans, M. and Werblin, F., 1992).

1.13.3.3 Receptive Field

In cat and rabbit, HA collects from ~200 cones and indirectly though gap junction coupling from several hundred more (Wassle, H. *et al.*, 1987a), and HB collects directly from ~100 cones. The receptive field size is modulated by dopamine and by light

(Lankheet, M. J. *et al.*, 1990; Hampson, E. C. *et al.*, 1994; He, S. *et al.*, 2000). Due to its robust electrical coupling, the receptive field of HA is large, under some conditions extending far (about tenfold) beyond its dendritic field (Lankheet, M. J. *et al.*, 1990). The electrical coupling of HB is weaker so its receptive field is smaller, not extending much beyond the dendritic field (Vaney, D. I., 1991). Receptive fields of primate H1, H2, H3 are much smaller than the analogous types in other mammals. The H2 receptive field is larger, collecting from ~20 cones, analogous to HA in cat. The H1 has a proportionately smaller receptive field not much larger than its dendritic field, collecting from ~10 cones, consistent with the receptive field surround of midget bipolar and ganglion cells (Packer, O. S. and Dacey, D. M., 2002) (see Chapter Contributions of Bipolar Cells to Ganglion Cell Receptive Fields).

1.13.3.4 Feedback

Horizontal cells provide negative feedback to cones (Baylor, D. A. *et al.*, 1971; Verweij, J. *et al.*, 2003; Tatsukawa, T. *et al.*, 2005) generating a cone surround. This feedback contributes to the surround in bipolar cells, and in some species horizontal cells are thought to be mainly responsible for the receptive field surround of ganglion cells such as the primate parasol cell (McMahon, M. J. *et al.*, 2004). Thus, surround feedback from horizontal cells is an important component of adaptation for all other neurons in the retina. In turtle and fishes, horizontal cell feedback generates color opponency in cones (Kamermans, M. *et al.*, 1991).

1.13.3.5 Feedback Mechanisms

Several mechanisms have been proposed for the feedback from horizontal cells to photoreceptors. Horizontal cells contain GAD, the synthetic enzyme for GABA (Vardi, N. *et al.*, 1994), and release GABA through a nonvesicular transporter mechanism (Schwartz, E. A., 2002). The classical feedback mechanism is that GABA released by horizontal cells modulates GABA-gated chloride channels in the photoreceptor membrane (Tachibana, M. and Kaneko, A., 1984; Wu, S. M., 1992; Dong, C. J. *et al.*, 1994; Liu, J. *et al.*, 2005). This mechanism has been found in several species (turtle, fishes, frog, and salamander), and may exist in some form in all vertebrates. An alternate mechanism has been proposed involving proton (pH) feedback from horizontal cells to the photoreceptor terminal (Hirasawa, H. and Kaneko, A., 2003; Tatsukawa, T. *et al.*, 2005). Another alternate mechanism, ephaptic (electrical) feedback has also been proposed (Byzov, A. L. and Shura-Bura, T. M., 1986; Kamermans, M. and Fahrenfort, I., 2004; McMahon, M. J. *et al.*, 2004).

1.13.3.6 Ephaptic Feedback

In the proposed ephaptic mechanism, the horizontal cell signal is relayed back to the cone terminal by the action of the current flow in the extracellular space of the photoreceptor terminal's invagination. When a remote spot of light hyperpolarizes the horizontal cell, current flow at cone terminals outside the spot increases from extracellular space into the horizontal cell's dendritic tip. This current causes a small negative shift in the voltage on the external surface of the cone's membrane in the invagination, which affects calcium channels in the membrane as a depolarization, thus generating negative feedback. The magnitude of the voltage shift depends on the electrical resistance of the extracellular space in the cone terminal's invagination. However, the opposite effect occurs at a cone terminal under a spot of light. In this case, light hyperpolarizes the cone terminal, reducing current flow into the horizontal cell's dendritic tip. This causes a positive shift in the voltage on the external surface of the cone's membrane, which appears to channels in the cone membrane as a hyperpolarization, generating positive feedback from a cone terminal back to itself. Horizontal cell dendrites also contain hemichannel gap junctions (i.e., connexin molecules), which are thought to be involved in the feedback because the application of carbenoxolone, a gap junction blocker, reduces the feedback signal (Kamermans, M. and Fahrenfort, I., 2004). This is also observed in animals where the gene encoding for the connexin molecule is knocked out. Because the hemichannels are not modulated by glutamate, the current through them shunts the glutamate-gated ion channels, reducing the gain of the light response, but shifting the balance in favor of negative feedback (Fahrenfort, I. *et al.*, 2005). In addition, the hemichannels may be modulated by voltage, complicating the mechanism (DeVries, S. H. and Schwartz, E. A., 1992). This postulated ephaptic feedback mechanism is controversial because it relies on a very narrow extracellular space in the cone terminal to produce a high resistance to the flow of current (Dmitriev, A. V. and Mangel, S. C., 2006).

1.13.3.7 Feedforward

There is also evidence for a direct GABAergic synaptic connection from horizontal cells to ON and OFF bipolar cells, enhancing their surround (Wu, S. M., 1992). Both ON and OFF bipolar types have GABA-A receptors on their dendrites (Vardi, N. and Sterling, P., 1994). For the ON bipolar cell, this implies a depolarizing chloride potential (see Figure 2) (Vardi, N. *et al.*, 2000; Duebel, J. *et al.*, 2006). Since the OFF bipolar cell dendritic tip is not directly adjacent to horizontal cell dendritic tips, to gate the GABA receptors located on OFF bipolar cell dendrites, the GABA released from horizontal cells would need to diffuse 1–2 μm (Vardi, N. and Sterling, P., 1994).

1.13.3.8 Rod Horizontal Cell

The HBAT in cat and rabbit receives input from 1000 to 2000 rods, most but not all in its field (Boycott, B. B. *et al.*, 1978; Pan, F. and Massey, S. C., 2007), with high gain and extensive electrical coupling, modulated like other horizontal cells by dopamine (Foerster, M. H. *et al.*, 1977; Vaney, D. I., 1993; Reitsamer, H. A. *et al.*, 2006), so it is ideally constructed to generate a smooth average rod signal at very low scotopic (starlight) backgrounds. Because the rod ribbon synapse is binary and transmits either a signal from one photon or none (Berntson, A. *et al.*, 2004), it is critically dependent on the tiny single photon signal to generate a discriminable slowing of glutamate release in a sea of thermal noise (Schein, S. and Ahmad, K. M., 2005). The single photon signal is only ~1 mV in amplitude so the rod terminal voltage must be regulated closely, within ~0.2 mV, to allow the binary synapse to function correctly (Berntson, A. *et al.*, 2004). Therefore, the HBAT seems likely to provide negative feedback, critical for modulating within the narrow voltage range the rod's release of glutamate. A feedback signal when summed with the rod's photon signal would traverse the rod→rod bipolar synapse, which has a nonlinear threshold on its postsynaptic side (van Rossum, M. C. and Smith, R. G., 1998; Field, G. D. *et al.*, 2005). Therefore, this feedback would generate a nonlinear surround, consistent with measurements of the ganglion cell hidden surround at low scotopic backgrounds (Wiesel, T. N. and Hubel, D. H., 1966; Barlow, H. B. and Levick, W. R., 1976).

1.13.4 Function of Horizontal Cell Circuit

1.13.4.1 Rationale for Outer Plexiform Layer: Noise Limits Information

A major problem facing the retina is that noise mixed with the visual signal limits information capacity (Barlow, H. B., 1981; Brenner, N. *et al.*, 2000; Abshire, P. A. and Andreou, A. G., 2001). The signal transmitted to the ganglion cell traverses two noisy ribbon synapses; one in the photoreceptor and the other in the bipolar cell. In daylight, the noise from the bipolar ribbon synapse is responsible for most of the noise recorded in the ganglion cell (Freed, M.A., 2000; van Rossum, M. C. *et al.*, 2003). To maximize the signal-to-noise (S/N) ratio in the ganglion cell, the OPL must modulate the photoreceptor signal to precisely set the synaptic gain, saturation, and basal release rate, and the horizontal cell is thought to provide the necessary feedback signal. But the feedback signal also contains noise (Freed, M. A. *et al.*, 2003), suggesting that horizontal cells are coupled to reduce it.

1.13.4.2 A Spatiotemporal Bandpass Filter

The horizontal cell is an essential part of the OPL circuit, which comprises a spatiotemporal bandpass filter and several adaptational mechanisms (Smith, R. G., 1995; van Hateren, H., 2005). The OPL removes the least essential signal components: the very high and very low frequencies, and the background light level. The remaining signal components therefore more fully modulate the photoreceptor signal's dynamic range. The horizontal cell generates a spatially low-pass response by collecting signals from an extended field of cones. The horizontal cell's output signal accumulates a temporal low-pass characteristic because it is filtered by the membrane time constants and synaptic delays in both photoreceptor and horizontal cell. This signal modulates glutamate release from photoreceptors through negative feedback, which removes low spatial and temporal frequencies. Current injected into the horizontal cell produces a similar effect to a light stimulus superimposed on the ganglion cell receptive field surround, directly implicating the horizontal cell's role (Mangel, S. C., 1991). The feedback prevents the photoreceptor's synaptic signal from saturating, which maximizes its sensitivity. The remaining signal transmitted to bipolar and ganglion cells is transient, spatially antagonistic, and contains mostly information about contrast (see Chapter Contributions of Bipolar Cells to

Ganglion Cell Receptive Fields). Thus, the OPL shapes the signal transmitted to ganglion cells to maximize their S/N ratio.

1.13.4.3 Feedback Loop

The negative feedback loop between photoreceptors and horizontal cell is important for the retina's ability to respond reliably under different lighting and physiological conditions. The negative feedback stabilizes the release rate of glutamate-filled vesicles by the ribbon synapse (Wu, S. M., 1992; Morgans, C. W., 2000). An increase in glutamate released by cones at dim intensities causes a stronger feedback signal from horizontal cells, leading to a partial restoration to the original level of release. The feedback is thought to have subtractive and divisive components, both of which contribute to adaptation. The feedback pathway from cone to horizontal cell includes a substantial (~10 ms) time delay, which at high frequencies (40–80 Hz) causes a 180° phase lag, inverting the feedback sign to positive. Therefore, the feedback loop can become unstable and oscillate, which occurs under some common conditions (e.g., low luminance, high contrast, opaque mask centered on receptive field; Foerster, M. H. *et al.*, 1977; Smith, V. C. *et al.*, 2001). Thus, to preserve stability, the loop gain (the product of the feedforward and feedback synaptic gains) must be limited. Because the feedforward synaptic gain from photoreceptors to horizontal cells is relatively strong (Belgum, J. H. and Copenhagen, D. R., 1988), the feedback gain must be weak (Smith, R. G., 1995; van Hateren, H., 2005).

1.13.4.4 Dynamic Modulation of Receptive Field

To reduce noise in the feedback signal, the horizontal cell collects a signal from many photoreceptors. The exact number is set by the conductance of its interconnecting gap junctions, which varies with background light intensity and stimulus contrast and shape (Lankheet, M. J. *et al.*, 1990; Reifsnider, E. S. and Tranchina, D., 1995; Xin, D. and Bloomfield, S. A., 1999). When measured with a bar flashed on and off at different positions, the HA receptive field is about tenfold larger then when measured with spots of different sizes centered on the receptive field (Lankheet, M. J. *et al.*, 1990). The explanation is that with a dark background, narrow spots or bars flashed at different positions do not adapt the retina much, dopamine remains at a low level, and gap junctions between horizontal cells remain open. But with the brighter light from a spot of increasing diameter, amacrine cells in the inner retina release dopamine, which closes gap junctions between horizontal cells (Baldridge, W. H. *et al.*, 1998; Xin, D. and Bloomfield, S. A., 1999). Electrical coupling is known to have a noise-reducing role (Lamb, T. D. and Simon, E. J., 1976; DeVries, S. *et al.*, 2002), suggesting the hypothesis that horizontal cell coupling is varied according to the need for noise reduction (Balboa, R. M. and Grzywacz, N. M., 2000). This is consistent with the noise properties of the retina because different background intensities generate different amounts of noise reflected in ganglion cell responses (Freed, M. A., 2000).

1.13.4.5 Contribution of Neuron Types

Receptive fields of the two types of horizontal cell have different profiles (Figure 3). The HA receptive field, when extended beyond the cell's dendritic field by gap junction coupling, is exponential in form (Bessel function) (Lamb, T. D. and Simon, E. J., 1976; Golard, A. *et al.*, 1992). The HB dendritic field is smaller, and coupling extends its receptive field less, so its receptive field is also smaller and more Gaussian. Because horizontal cells of both HA/H2 and HB/H1 feedback to the same cones, the surround passed on to the bipolar cell is likely to include contributions of both depending on the relative amplitude of their responses (Smith, R. G., 1995; Shen, Y. *et al.*, 2003) (Figure 2). Mixing of their receptive fields, each with a different spatial extent (Reifsnider, E. S. and Tranchina, D., 1995) may shape the bipolar cell surround to optimally filter and remove noise. The strength of feedback, and thus the depth of its contribution to the bipolar cell and ganglion cell surround, is limited to avoid oscillatory instability (Smith, R. G., 1995; van Hateren, H., 2005). But the contribution from inhibitory feedforward connections lacks this limitation and so may be deeper. The bipolar cell surround is also deepened by feedback from amacrine cells in the inner plexiform layer. The relative amplitude and extent of the surround components originating in horizontal versus amacrine cells is thought to vary dynamically according to background intensity and type of stimulus (Cook, P. B. and McReynolds, J. S., 1998; McMahon, M. J. *et al.*, 2004; Ichinose, T. and Lukasiewicz, P. D., 2005). Because wide-field amacrine cells extend farther, their surround contribution is shallower but wider (see Chapter Amacrine Cells).

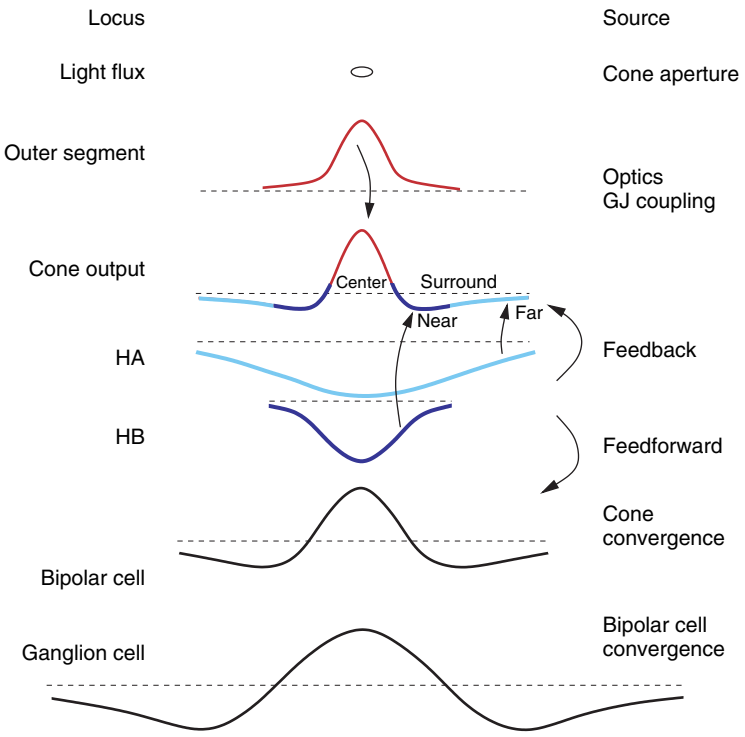

Figure 3 Horizontal cells contribute to receptive field surround of bipolar cell and ganglion cell. Left column: locus in different layers for measuring receptive field. Right column: source of changes between one layer and the next. When probed by a spot or bar at different locations, the cone receptive field has center surround organization. Top: center Gaussian component (~3 μm in primate and ~20 μm in cat) originates in cone aperture (~2 μm) and blur from the optics of the eye and gap junction coupling. Receptive field of horizontal cell is large because it collects directly from 100 to 200 cones, and indirectly from several hundred more through lateral coupling. Antagonistic surround in cone receptive field originates in feedback from HA (large) and HB (small) horizontal cells. HB feedback generates near surround, and HA feedback generates far surround. Profile of surround is a mixture of both the HA and the HB components and changes dynamically with stimulus. Receptive field center of bipolar cell (20–50 μm) is larger than cone center because the bipolar cell collects from several cones. Strength of bipolar surround is increased relative to the center by feedforward from horizontal cell and because the summed cone surrounds overlap more than the centers. Receptive field center of ganglion cell is wider (50–500 μm) because its dendritic field collects from many bipolar cells and its surround is stronger because the bipolar surrounds heavily overlap. Amacrine cells (not illustrated) provide additional surround feedback to bipolar cells and feedforward to ganglion cell. Receptive field profiles are normalized to same peak amplitude. Spatial extent of centers and surrounds is not drawn to scale.

1.13.5 Conclusion

Horizontal cells contribute to the ganglion cell receptive field surround through their feedforward and feedback connections. In this role, horizontal cells remove low spatial and temporal frequencies from the visual signal passed to the brain. In some species horizontal cells provide a color-opponent signal. But horizontal cells provide a more basic influence. The horizontal cell circuit computes a local average signal, which precisely regulates the photoreceptor's synaptic release thus preventing saturation, implying that the horizontal cell's function is to reduce noise and improve the quality of the ganglion cell signal.

Glossary

contrast sensitivity The reciprocal of the contrast required to reach a criterion spike rate.

convolution A mathematical operation on two functions that determines how the shape of one is blurred by that of the other.

quantum The amount of transmitter packaged in a single vesicle.

1.14.1 Introduction

Every bipolar cell has an elongated cell body with dendrites at the top that contact photoreceptors and an axon terminal at the bottom that contacts amacrine and ganglion cells; thus it conveys information from the photoreceptor axon terminals (rod and cone) to ganglion cell dendrites in the inner plexiform layer (IPL).

Information is conveyed from bipolar cell to ganglion cell by chemical synapses that release glutamate in packets called quanta. Glutamate binds to receptors in the ganglion cell membrane and opens conductances for cations (mostly sodium (Na^+) and potassium (K^+)). Thus currents flow along dendrites until they reach the cell body and then the thin segment of the axon, where they charge up the membrane and initiate a spike. Because photoreceptors form a regular array across the retina, and transmit information through bipolar cells, the pattern of light across this array controls the pattern of glutamate quanta across ganglion cell dendrites, and thus controls the ganglion cell's spike transmission to the brain.

Bipolar cells constitute a set of parallel channels, each transmitting a different kind of information. Ganglion cells choose from among different bipolar cell types, sometimes relaying this information relatively unchanged, sometimes recombining information, and project this information to different

areas of the brain. This chapter focuses on how bipolar cells contribute to the ganglion cell's encoding of information about objects of different size (spatial frequency) and of different temporal properties.

1.14.2 About 10 Types of Bipolar Cell

There are about 9–13 types of bipolar cell, depending on the animal that end in distinct levels of the IPL (Boycott, B. B. and Wässle, H., 1991; Kolb, H. *et al.*, 1992; Ghosh, K. K. *et al.*, 2004; MacNeil, M. A. *et al.*, 2004; Pignatelli, V. and Strettoi, E., 2004). About half these types signal increases in contrast (On) and about half signal decreases in contrast (Off). On and Off bipolar cells can be aggregated into four basic groups that transmit different information. On and Off midget bipolar cells serve a perception of fine detail and may serve red/green opponency (Calkins, D. J. and Sterling, P., 1999; Martin, P. R., 1998; Dacey, D. M. and Packer, O. S., 2003). The On S bipolar cell contributes the blue component of blue/yellow opponency (Dacey, D. M. and Lee, B. B., 1994; Calkins, D. J. *et al.*, 1998; Calkins, D. J., 2001; Herr, S. *et al.*, 2003). The rod bipolar cell contributes sensitivity to very dim illumination (scotopic). On and Off diffuse bipolar cells contact multiple cones of mixed type and initiate temporal and spatial frequency channels. Unless otherwise stated, in the following discussion, bipolar cell will mean diffuse bipolar cell.

1.14.3 Bipolar Cells Contribute to Spatial Frequency Channels

1.14.3.1 Receptive Field is a Convolution

The eye's lens projects a receptive field onto the array of photoreceptors that is wired to a ganglion cell. The distribution of sensitivity across this receptive field looks like a Mexican hat; the hat's cross-section has been described as the difference of two Gaussians: one for the receptive field center, the other for the surround (Rodieck, R. and Stone, J., 1965; Enroth-Cugell, C. and Robson, J., 1966). It is this distribution that set a ganglion cell's spatial frequency selectivity.

To understand how a bipolar cell contributes to the ganglion cell's receptive field, consider a convolution model with two components (Figure 1(a)). First, bipolar receptive fields have a difference of Gaussians distribution of sensitivity and form a regularly spaced array. Second, the distribution of membrane area across the diameter of a dendritic tree is domed-shaped, and so too is the distribution of bipolar synapses, approximating a Gaussian weighting function (Kier, C. K. *et al.*, 1995). To combine these components, we convolve the bipolar receptive field center with the weighting function; we do the same for the bipolar receptive field surround. For either convolution, the result is a Gaussian. Furthermore, if σ_{bp} is a standard deviation for the bipolar receptive field (either center or surround) and σ_{dend} the standard deviation of the weighting function, then the standard deviation for the ganglion cell is $\sigma_{gc} = \sqrt{\sigma_{bp}^2 + \sigma_{dend}^2}$. It is significant that the standard deviation for the ganglion cell approximates the larger of the two component standard deviations.

The convolution model works out very differently for α and β cells of the cat retina and accurately predicts their sensitivity distributions (Freed, M. A. *et al.*, 1992; Figure 1(b)). In the area of central vision, both cells receive synapses from the same bipolar cell type that has a $\sigma_{bp\ center} \approx 20\,\mu m$, and $\sigma_{bp\ surround} \approx 130\,\mu m$. The α cell has a large dendritic arbor with $\sigma_{dend} \approx 50\,\mu m$. As a result of the convolution, the α center approximates its dendritic arbor, but its surround approximates the bipolar surround. The β cell has a small dendritic arbor with $\sigma_{dend} \approx 10\,\mu m$, and consequently its center and surround matches those of the bipolar cell.

The size of a ganglion cell's receptive field determines its spatial frequency selectivity, that is, its preference for stimuli of a particular size. Thus for large ganglion cells, selectivity is determined by the dendritic arbor, but for small ganglion cells selectivity is determined by the size of the bipolar receptive field. There is no evidence for a wide variety of bipolar receptive field sizes (Dacey, D. *et al.*, 2000), so they do not initiate spatial frequency channels; instead such channels result from ganglion cell dendritic trees.

1.14.3.2 Random Properties of Bipolar Array

Convolution models help us conceptualize the relation between dendritic tree size and receptive field size. But detailed mappings show that some ganglion cell sensitivity distributions are not smooth like a Gaussian but asymmetric and bumpy (Rodieck, R. and Stone, J., 1965; Peichl, L. and Wässle, H., 1979; Soodak, R. E. *et al.*, 1991; Brown, S. P. *et al.*, 2000). These bumps result from

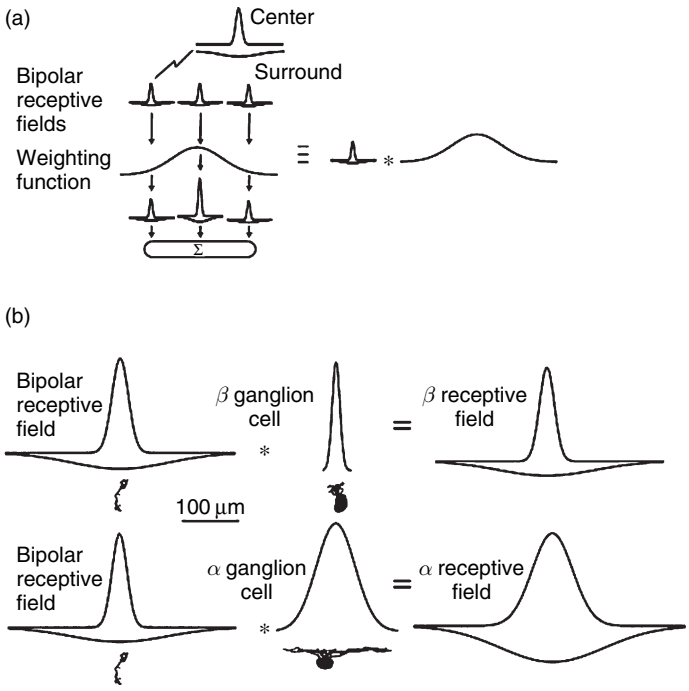

Figure 1 Contribution of bipolar cells to ganglion cell receptive field: convolution model. (a) Weighted summation. Bipolar receptive fields, each consisting of center and surround Gaussians, are scaled according to the local value of a weighting function, and then summed. This is identical to a convolution (∗) between receptive field and weighting function. (b) Convolution models of α- and β-cell receptive fields. The bipolar receptive field ($\sigma_{center} = 20$ mm; $\sigma_{surround} = 130$ μm) is convolved with a Gaussian that approximates the distribution of membrane across the α and β dendritic trees ($\sigma_{dend} \sim 50$ and 10 μm, respectively). As predicted by this model, the α receptive field center is enlarged and its surround is deepened but the β receptive field matches that of the bipolar cell. Adapted from Freed, M. A. and Sterling, P. 1988. The On-alpha ganglion cell of the cat retina and its presynaptic cell types. J. Neurosci. 8, 2303–2320; Kier, C. K., Buchsbaum, G., and Sterling, P. 1995. How retinal microcircuits scale for ganglion-cells of different size. J. Neurosci. 15, 7673–7683.

irregularities in the weighting function, which have several causes: bipolar cells form a somewhat disorderly array across the retina; not every bipolar cell in this array contacts a ganglion cell; the number of synapses each bipolar cell contributes varies (Freed, M. A. *et al.*, 1992). Further, some ganglion cells have large dendritic trees whose electrical structure may be complex: synapses at different loci in the dendritic tree may contribute different amounts of current to the spike initiation site at the axon's thin segment; spikes may be initiated throughout the dendritic tree (Velte, T. J. and Masland, R. H., 1999). Finally, ganglion cells receive amacrine input that the model does not account for. Thus a more complex model with an irregular weighting function that departs from a smooth Gaussian is necessary to explain the ganglion cells sensitivity distribution (Figure 2).

The sensitivity distribution across small receptive fields tends to be smoother than the distribution across larger receptive fields (Brown, S. P. *et al.*, 2000). This is probably because a small receptive field is the result of a small dendritic arbor: thus irregularities in the small weighting function are smoothed out by convolution with the larger bipolar receptive field. Some cells, such as the β cell of the cat retina, receive input from several overlapping bipolar cell arrays, which smoothes the weighting function.

Bumps can vary substantially from one ganglion cell to another of the same type. An extreme example is the bistratified blue/yellow ganglion cell, whose sensitivity distribution is sometimes dominated by a single S cone and sometimes by several S cones (Chichilnisky, E. J. and Baylor, D. A., 1999). This variability is probably due to variability in the strength of synaptic connections between a single S cone and several S bipolar cells (Schein, S. *et al.*, 2004). These bumps are not likely to be smoothed by the optics of the eye: the eye's blurring function is smaller than any of the receptive field components (<4 μm), and thus when convolved with these components, has little effect (Navarro, R. *et al.*, 1993). Such random irregularities are likely to be of

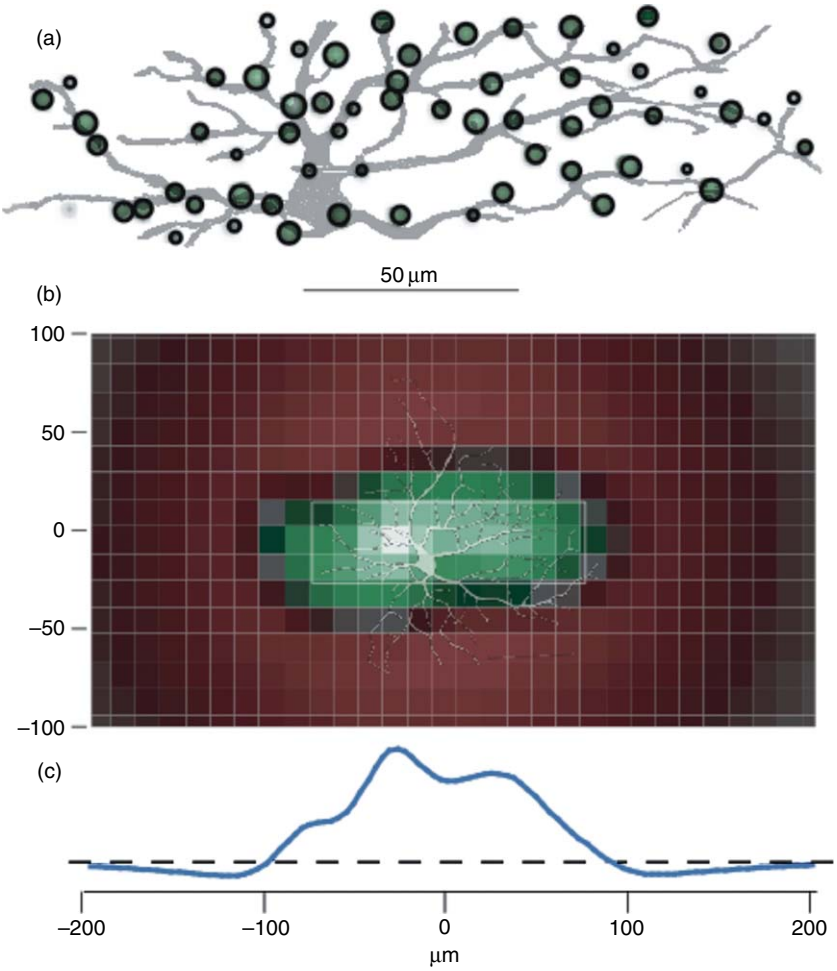

Figure 2 Contribution of bipolar cells to ganglion cell receptive field: detailed model. (a) A partial reconstruction of the dendritic arbor from ultra thin (80 nm) sections. An array of 74 diffuse cone bipolar cells of type b1 crossed the dendritic tree; the green disks represent 62 of these that synapsed on the α cell. Disk diameter is proportional to weighting, which is the product of the number of synapses and the effectiveness of each synapse at triggering a spike, as estimated from a compartmental model of the α cell. (b) Weighted summation of bipolar receptive fields: predicted α center is green (highest values are white), while the predicted surround is red. (c) A horizontal slice of the predicted receptive field. Bipolar cells outside the reconstructed region were omitted, but because the slice is centered on the region and parallel to it, this omission is inconsequential. The distribution of sensitivity shows asymmetry and bumps due to irregularities in the weighting function (compare to effect of smooth Gaussian weighting function in Figure 1). Adapted from Freed, M. A., Smith, R. G., and Sterling, P. 1992. Computational model of the on-alpha ganglion cell receptive field based on bipolar cell circuitry. Proc. Natl. Acad. Sci. U. S. A. 89, 236–240.

consequence to information decoding because the relationship between spike rate and the position or size of an object is inconsistent across ganglion cells.

1.14.3.3 Adaptive Properties of Bipolar Array

The bumps in a receptive field profile can adapt to a visual environment in order to increase sensitivity when the environment changes. During this adaptation, sensitivity changes within small subregions about the size of a bipolar cell receptive field, suggesting that adaptation is due to changes in bipolar cell sensitivity (Brown, S. P. and Masland, R. H., 2001; Baccus, S. A. and Meister, M., 2002; Hosoya, T. *et al.*, 2005). Bipolar cells are known to adapt and change sensitivity by an intrinsic mechanism that requires intracellular calcium (Shiells, R. A. and Falk, G., 1999; Rieke, F., 2001).

1.14.3.4 Contribution to Peak Contrast Sensitivity

The density of bipolar cell synapses on cellular membrane is $10\,\mu m^{-2}$ for α cells, about $30\,\mu m^{-2}$ for β cells of the cat retina. Furthermore, small β trees cover the retina about three times more densely with membrane than large α trees (Kier, C. K. *et al.*, 1995). Correspondingly, when peak contrast sensitivity is measured at the middle of the Gaussian receptive field center, cells with the smallest receptive fields (β) have about nine times higher peak contrast sensitivity than those with large receptive fields (α), suggesting that the number of bipolar synapses activated by a stimulus contributes to sensitivity. Smaller cells may have greater peak sensitivity for additional reasons: synaptic currents may have a shorter distance to reach the spike initiation site, which combined with a higher input resistance, would produce a larger voltage (O'Brien, B. J. *et al.*, 2002).

1.14.3.5 Contribution to Contrast Threshold

The total number of bipolar synapses should also set the lowest detectible contrast by setting the signal-to-noise ratio. This is because synaptic release is a Poisson process, for which the signal is the mean rate of quantal release n, and the noise is $\sqrt{n}$, so the signal-to-noise ratio is $\sqrt{n}$. By inference, ganglion cells that receive many bipolar cell synapses, presumably with a high mean rate n, provide a high signal-to-noise ratio. This inference appears to be true for at least one ganglion cell type: large β cells with many synapses have higher signal-to-noise ratios than small β cells with fewer synapses (Freed, M. A., 2000a). A study designed to test this inference for primate ganglion cells failed to confirm it, although this may have been due to a sinusoidal stimulus that increases and decreases synaptic noise every period, and thus shows no net difference (Croner, L. J. *et al.*, 1993).

1.14.4 Bipolar Cells Contribute to Nonlinear Subunits

1.14.4.1 Counter-Phased Grating Reveals Nonlinear Subunits

A counter-phased grating is an alternating series of light and dark bars: dark bars are exchanged for light bars and vice versa (Figure 3). If the grating is fine enough, many ganglion cells will fire at every exchange (Hochstein, S. and Shapley, R. M., 1976). This behavior, called frequency doubling has been attributed to an array of nonlinear subunits within the receptive field center and beyond. These subunits resemble, by their array and sensitivity to fine gratings, the array of bipolar cell receptive fields. Only subunits within the receptive field center persist when amacrine synapses are blocked, indicating that

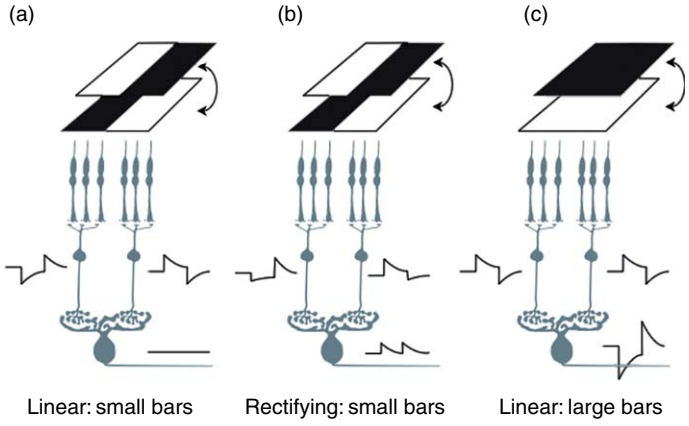

Figure 3 Contribution of bipolar cells to nonlinear subunits in the ganglion cell receptive field. (a) Linear responses, small bars: response to dark bar exchanging for light and response to light bar exchanging for dark are equal and opposite (the figure shows responses to a complete cycle of two exchanges). The result is no net ganglion cell response. (b) Rectifying responses, small bars: Response to dark bar exchanging for light is greater than response to light bar exchanging for dark: the result is a net response at each exchange. (c) Linear responses, large bars: for a large bar, the responses from the two bipolar cells are identical. The result is a large net response. Thus linear component of bipolar cell responses contributes selectivity to low spatial frequencies (≈ large bars) characteristic of ganglion cell's receptive field center and surround; rectifying response component contributes to sensitivity to high spatial frequencies (≈ small bars) characteristic of ganglion cells nonlinear subunits.

these subunits are transmitted through bipolar synapses on the ganglion cell; those beyond the center apparently require transmission by spiking amacrine cells, but may also originate, at least in part, in bipolar cells (Demb, J. B. *et al.*, 2001).

Rectifying and thus nonlinear bipolar cell responses are thought to contribute nonlinear subunits. A linear bipolar cell response would contribute sensitivity to low spatial frequencies characteristic of the receptive field center and surround (Figure 3). Because a given bipolar cell's response is never completely linear, the same bipolar cell could contribute to center, surround, and subunit in the ganglion cell receptive field. Subunits have at least one important consequence: a ganglion cell with a large receptive field can encode information about high spatial frequencies.

1.14.5 Bipolar Cells May Initiate Temporal Frequency Channels

1.14.5.1 Temporal Frequency Response of Bipolar Cells

Different types of ganglion cell have different temporal bandwidth, that is, respond to different ranges of temporal frequency. Bipolar cells show sustained and transient responses, corresponding to low and high frequencies. This suggests that bipolar cells initiate temporal frequency channels and impart their temporal tuning to ganglion cells. Yet the temporal tuning of only few bipolar types has been characterized.

In lieu of tuning curves for every bipolar cell type, it is tempting to infer each type's frequency response from the frequency response of ganglion cells that branch in the same stratum. But most bipolar types overlap several distinct frequency responses (MacNeil, M. A. *et al.*, 2004). It has been suggested that transient bipolar cells are in the middle of the IPL and sustained at the edges (Awatramani, G. B. and Slaughter, M. M., 2000; Roska, B. and Werblin, F., 2001), but it would be surprising if this were generally true because in some retinas a sustained (local edge) ganglion cell branches in the middle and a transient (α) ganglion cell branches at the edges (Rockhill, R. L. *et al.*, 2002).

A conceptual scheme shows how frequency channels, established by bipolar cells, may feed through different ganglion cell types to the brain (Figure 4). Narrowly tuned ganglion cells, selective for high or low frequencies, may select from narrowly tuned bipolar cells. Broadly tuned ganglion cells may select both high- and low-frequency bipolar cells. This scheme avoids the need for extra types of broadly tuned bipolar cells, which would require them to have greater bandwidth.

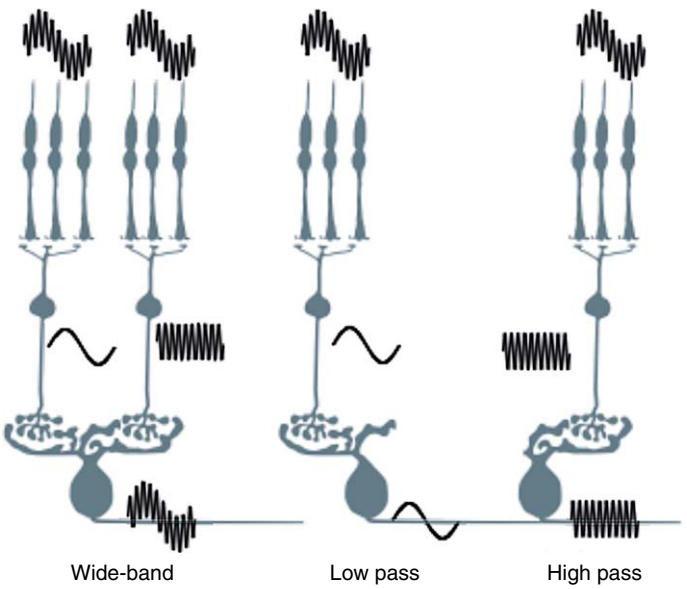

Figure 4 Contribution of bipolar cells to temporal frequency tuning of ganglion cells. Both high and low frequencies appear in the visual stimulus (shown here as a sum of sinusoids). The bipolar cell types decompose the signal into high and low frequencies. Wide-band ganglion cells receive synapses from both types of bipolar cell: low-pass and high-pass ganglion cells receive from low- and high-frequency bipolar cells, respectively.

1.14.5.2 A Bipolar Cell's Intrinsic Properties Modify Its Frequency Response

A bipolar cell's frequency tuning cannot be a function of the cones it contacts, because both sustained and transient diffuse bipolar cells contact the same cones. Instead, frequency tuning must be intrinsic to the bipolar cell or its synaptic interactions with amacrine cells. For example, all bipolar cells receive an inhibitory gamma-aminobutyric acid (GABA)ergic synapse from an amacrine cell, often the bipolar cell reciprocates with an excitatory glutamatergic synapse onto the amacrine cell, thus implementing a negative feedback loop. Some bipolar cells have $GABA_C$ receptors with slow kinetics that allow low frequencies to pass, others have $GABA_A$ that block low frequencies (Lukasiewicz, P. D. *et al.*, 1994; Euler, T. and Wassle, H., 1998; Freed, M. A. *et al.*, 2003). $GABA_B$ receptors modulate calcium currents and thus may alter release kinetics (Maguire, G. *et al.*, 1989).

Three different types of Off bipolar cell in the 13-lined ground squirrel use three distinct receptor types to sense glutamate release from the cone: two of the kainate type, one of the α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) type. All these receptors desensitize when continuously exposed to glutamate, but the AMPA receptor has the speediest recovery from desensitization (DeVries, S. H., 2000). Because cones release glutamate continuously in the dark, and presumably desensitize the receptor, and because light decreases release and allows recovery from desensitization, the AMPA receptors confer a speedier response to light, and thus sensitivity to higher frequencies.

Other intrinsic properties may modify the signal a bipolar cell transmits to a ganglion cell. Calcium channels within the axon terminal control release of glutamate onto a ganglion cells, may be either of transient (T) or sustained (L) properties, and may confer these properties to the ganglion cell (de la Villa, P. *et al.*, 1998; Pan, Z. H. *et al.*, 2001). Metabotropic autoreceptors on a bipolar cell sense its own glutamate release and modify release kinetics (Koulen, P. *et al.*, 1999).

1.14.5.3 On and Off Bipolar Cells Initiate Matched Temporal Channels

On and Off ganglion cells with similar morphology have similar response kinetics, with only small consistent differences (Chichilnisky, E. J. and Kalmar, R. S., 2002; Zaghloul, K. A. *et al.*, 2003). This is remarkable given that these responses come from different bipolar cells with entirely different mechanisms for transmitting signals. Transmission by On bipolar cells requires many steps: when glutamate from cones binds to its receptor, this initiates a multistep biochemical cascade that closes cation channels. Transmission by Off bipolar cells is simpler: when glutamate binds to its receptor, this closes a cation channel that is integral to the receptor. Despite the extra steps, On bipolar and ganglion cells are about as fast as Off cells (within 10 ms) and sometimes faster (Shiells, R. A. and Falk, G., 1994; Chichilnisky, E. J. and Kalmar, R. S., 2002; Zaghloul, K. A. *et al.*, 2003). Thus On and Off bipolar cells use different neural circuits and intrinsic mechanisms to initiate a set of approximately matched On and Off temporal channels.

1.14.6 Contribution of Bipolar Cells to Information Encoding

1.14.6.1 Contribution to Linear Responses

To ensure a spike train with adequate information entropy, spike rate must fluctuate up and down. But if synapses were to saturate, this would prevent fluctuation, and thus reduce information content. Bipolar cells prevent saturation at the synapse by releasing glutamate quanta at moderate rates. The dendritic tree of a medium-sized ganglion cell receives about 2000 bipolar synapses. During a just-maximal response to a high-contrast bar, these synapses collectively release about 40 000 quanta s^{-1} (Freed, M. A., 2000b; Freed, M. A. *et al.*, 2003). But a synapse releases only about 20 quanta s^{-1}. During more moderate responses to naturalistic stimuli, a synapse releases at even lower rate, only about 0.1 quanta s^{-1}, which is a quantum every 10 s (Freed, M. A., 2005)! In order to have an overlapping effect on the ganglion cell voltage quanta must be within an integration time of about 20 ms. Thus quanta at a synapse very rarely overlap, and the conductance at a synapse is kept well below the peak conductance caused by a quantum, about 100 pS. Such low conductances forestall saturation of the synapse's driving force, and thus enhance information encoding (Freed, M. A. *et al.*, 1992; Freed, M. A., 2000b). Interestingly, bipolar cell synapses can release quanta at tremendous rates for short periods of time when triggered electrically, but apparently do not operate this way under natural conditions (500 s^{-1}; von Gersdorff, H. and Matthews, G., 1994; von Gersdorff, H. *et al.*, 1996).

1.14.6.2 Contribution to Information Encoding

The amount of information that a ganglion cell sends to the brain is critically limited by variability in spike timing. The bipolar cell must therefore time glutamate release accurately to trigger spikes accurately. Indeed both quanta and spikes, when evoked by naturalistic stimuli, have about the same average temporal accuracy, 10 ms, and for some cells, spike accuracy, and by inference quantal accuracy, is as good as 1 ms (Berry, M. J. and Meister, M., 1998; Freed, M. A., 2005).

The random nature of quantal release reduces the reliability of chemical synapses. Even if an identical signal appeared repeatedly in the bipolar cell, the number of quanta that are released will be variable; thus the resulting count of triggered spikes will also be variable. Reproducibility can be expressed as the mean count over the standard deviation (of spikes or quanta). For a Poisson process such as quantal release, if the average count is n, then the reproducibility is $\sqrt{n}$. For ganglion cell spiking, reproducibility is greater (Troy, J. B. and Robson, J. G., 1992; Berry, M. J. *et al.*, 1997; van Steveninck, R. R. D. *et al.*, 1997).

An array of bipolar cells reduces spike variability by synchronizing release across many synapses whenever the visual stimulus matches bipolar cell tuning (i.e., the bipolar cell's spatiotemporal filter). This results in bursts of quanta that, for a moderate contrast, can include as many as 60 quanta and which average about 20 quanta (Freed, M. A., 2005). But a ganglion cell fires bursts of only one to six spikes (Berry, M. J. *et al.*, 1997; Koch, K. *et al.*, 2004), indicating that many quanta trigger few spikes. The advantage of triggering with multiple quanta can be calculated from their Poisson statistics. If a single quantum reliably triggered a single spike, then both would have a reproducibility of 1. But for an average burst size of 20, quanta have a reproducibility of 4.5. Thus many quanta triggering few spikes increases the reproducibility of the spike train.

1.15.1 Morphological Diversity

By all measures, amacrine cells are the most diverse class of neurons in the retina and, in contrast to the other major classes of retinal neurons, no single statement adequately describes their structure or function. Both Cajal S. R. (1893) and Dogiel A. S. (1891) noted that the interneurons of the inner retina do not give rise to a classical axon, leading Cajal to name them amacrine cells, from the Greek *a-makrós-inos* meaning without long fiber. However, Cajal also recognized that some amacrine cells in the bird retina do give rise to a short intraretinal axon and these cells he called association amacrine cells, to distinguish them from amacrine cells proper. It has since become clear that there are numerous types of axon-bearing amacrine cells in the vertebrate retina (Vaney, D. I. *et al.*, 1988; Dacey, D. M., 1989; Famiglietti, E. V., 1992) and, in keeping with Cajal's broad view, the term amacrine cell now embraces all types of retinal interneurons that receive their synaptic input in the inner retina, including interplexiform cells (Vaney, D. I., 2003).

The input and output synapses of amacrine cells are typically located side by side on the dendrites, notwithstanding the minority of axon-bearing cells. Amacrine cells receive excitatory input from retinal bipolar cells and provide inhibitory output both to the dendrites of retinal ganglion cells and to the dendrites of other amacrine cells, as well as back to the axon terminals of bipolar cells. Thus, amacrine cells can modulate the activity of ganglion cells both postsynaptically, by inhibiting the ganglion cells directly, and presynaptically, by inhibiting the bipolar cells that provide the excitatory drive.

The mammalian retina has been conservatively estimated to contain about 30 morphological types of amacrine cells (Kolb, H. *et al.*, 1981; MacNeil, M. A. *et al.*, 1999; Figure 1). However, the recent identification of many novel types of axon-bearing amacrine cells, some represented by only a single example (Badea, T. C. and Nathans, J., 2004; Vaney, D. I., 2004; Lin, B. and Masland, R. H., 2006), indicates that more types remain to be characterized and that the number of distinct types of amacrine cells in the mammalian retina may well approach 50 or more (Vaney, D. I., 1990).

The numerous types of amacrine cells differ greatly in both their structure and cell density. At one extreme, the well-characterized AII amacrine cells account for over 10% of the amacrine cells and their narrow-field diffuse dendritic trees tile the retina with little overlap. At the other extreme, several types of axon-bearing amacrine cells account for only 0.1% of the amacrine cells, but their widely overlapping axonal fields, which may span ~10 mm of retina, create a very dense plexus. This is readily apparent for the dopaminergic amacrine cells, which were the first retinal neurons to be identified neurochemically (Häggendal, J. and Malmfors, T., 1965).

1.15.2 Neurochemical Diversity

Early histochemical and immunocytochemical studies highlighted the neurochemical diversity of the amacrine cells, with emphasis on the monoamine transmitters and neuropeptides (Brecha, N. *et al.*, 1979). However, virtually all amacrine cells contain elevated levels of glycine or GABA (Marc, R. E. *et al.*,

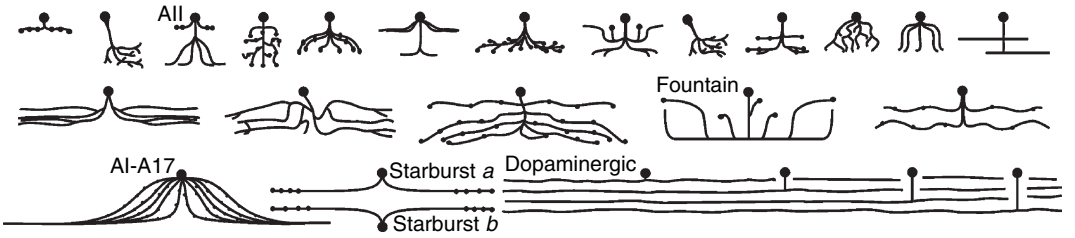

Figure 1 Diversity of amacrine cells in the mammalian retina. Schematic drawing of the different types of amacrine cells identified by MacNeil M. A. *et al*. (1999) using a photofilling technique in the rabbit retina. The cells are drawn as they would be seen in vertical section, with the somata in the inner nuclear layer and the dendrites in the inner plexiform layer. The multiple types of wide-field amacrine cells branching in each stratum are represented by a generic cell whose dendrites have been truncated. Labels mark specific types of amacrine cells referred to in the text. Masland, R. H. 2001. Neuronal diversity in the retina. Curr. Opin. Neurobiol. 11, 431–436.

1995), which may be colocalized with another neurotransmitter or neuromodulator. Most of the putative GABAergic cells express the GABA-synthesizing enzyme, glutamic acid decarboxylase, and most of the putative glycinergic cells express the plasma membrane glycine transporter, GlyT1. Although the glycinergic cells account for a small majority of amacrine cells in the mammalian retina (Figure 2), the inner plexiform layer is dominated by the processes of GABAergic amacrine cells, which usually have much more extensive dendritic trees than the glycinergic amacrine cells (Pourcho, R. G. and Goebel, D. J., 1983; Menger, N. *et al*., 1998). Correspondingly, the GABAergic cells account for 80–90% of the synapses made by all amacrine cells in the retina (Koontz, M. A. and Hendrickson, A. E., 1990; Marc, R. E. and Liu, W., 2000).

Both GABA and glycine are fast-acting inhibitory transmitters that gate closely related chloride-permeable channels. It is unclear why these amino acid transmitters are differentially distributed in the CNS, with GABA mediating most of the inhibition in the brain and glycine mediating most of the inhibition in the spinal cord. Uniquely within the CNS, the retina contains about equal numbers of GABAergic and glycinergic interneurons. An examination of the different roles of GABA and glycine in visual processing in the retina may cast light on why one or other of these inhibitory transmitters predominate in other parts of the CNS.

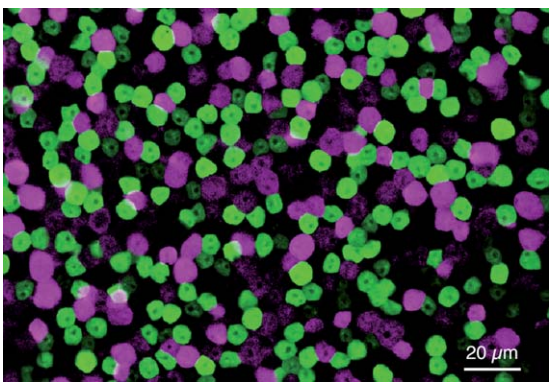

Figure 2 Almost all amacrine cells express glycine or GABA. Confocal fluorescence micrographs of a rabbit retinal wholemount immunolabeled for glycine (green) and GABA (magenta), with the focus on the amacrine sublayer of the inner nuclear layer (Wright, L. L. and Vaney, D. I., unpublished).

The glycinergic amacrine cells have small- or medium-field dendritic trees that typically occupy two or more strata of the inner plexiform layer and, therefore, can facilitate interactions between the parallel pathways established by the different types of cone bipolar cells (Pourcho, R. G. and Goebel, D. J., 1985). In other words, the glycinergic amacrine cells seem designed to mediate vertical inhibition in the retina (Roska, B. and Werblin, F., 2001). The GABAergic amacrine cells, by comparison, seem designed to mediate the lateral inhibition that has normally been attributed to amacrine cells, either via feedback inhibition of bipolar cells or via feedforward inhibition of ganglion cells and other amacrine cells (Roska, B. *et al*., 2000). Such a dichotomy does not appear to be rigid. The fountain amacrine cells, for example, are medium-field bistratified cells that contain GABA and probably substance P: their unusual morphological organization suggests that they receive input in the On sublamina and make output in the Off sublamina (MacNeil, M. A. *et al*., 1999; Wright, L. L. and Vaney, D. I., 1999).

Other neurotransmitters or neuromodulators expressed by amacrine cells are always colocalized with a fast-acting inhibitory transmitter, usually GABA but sometimes glycine, and the output synapses of these cells appear to be primarily

inhibitory. For example, the extensive synapses made by dopaminergic amacrine cells onto AII amacrine cells appear to be GABAergic, whereas the released dopamine diffuses to more distant receptors (Contini, M. and Raviola, E., 2003). Even the cholinergic starburst amacrine cells, which provided the definitive example of an excitatory amacrine cell, contain GABA (Vaney, D. I. and Young, H. M., 1988). Elegant dual-recording studies have shown that the inhibitory GABAergic inputs from starburst cells to each other and to retinal ganglion cells underlie the generation of direction selectivity in the retina (Fried, S. I. *et al.*, 2002; Lee, S. and Zhou, Z. J., 2006). Both GABA and acetylcholine may be released by starburst cells (O'Malley, D. M. *et al.*, 1992), but it remains an open question whether both transmitters are coreleased from the same synapses and under what circumstances.

Amacrine cells receive excitatory input from bipolar cells through ionotropic glutamate receptors; different amacrine types express distinct sets of NMDA, AMPA, and kainate receptors, which may be critical in shaping their temporal responses (Dumitrescu, O. N. *et al.*, 2006). Although the chemical synapses made by amacrine cells are primarily inhibitory, many types of amacrine cells also make excitatory electrical synapses through gap junctions. Different types of amacrine cells show different patterns of neuronal coupling (Vaney, D. I., 1994). Some types are homologously coupled to amacrine cells of the same type; others are heterologously coupled to amacrine cells of a different type or to specific types of retinal ganglion cells whose firing they help to synchronize (Mastronarde, D. N., 1989; Brivanlou, I. H. *et al.*, 1998).

1.15.3 Feedback and Feedforward Inhibition

Early physiological studies suggested that spatial visual processing takes place in the outer retina, through the actions of horizontal cells, and that temporal visual processing takes place in the inner retina, through the actions of amacrine cells (Werblin, F. S. and Dowling, J. E., 1969). However, recent work in amphibian and mammalian retinas makes it clear that the separate channels of temporal representation are first established in the outer retina (Awatramani, G. B. and Slaughter, M. M., 2000; DeVries, S. H., 2000). Conversely, although the receptive field surround is initially generated by horizontal cells in the outer retina (Mangel, S. C., 1991; McMahon, M. J. *et al.*, 2004), amacrine cells also make an important contribution in the inner retina (Cook, P. B. and McReynolds, J. S., 1998; Taylor, W. R., 1999).

One function of amacrine cells that has been closely investigated is their role in delivering inhibitory feedback to the axon terminals of bipolar cells. The transmitter used is GABA and both $GABA_A$ and $GABA_C$ receptors are thought to be involved. Pharmacological experiments and studies using $GABA_C$-knockout mice (McCall, M. A. *et al.*, 2002) show that the two receptor types have complementary functions. $GABA_A$ receptors activate quickly and provide fast and transient feedback while the intrinsically slower $GABA_C$ receptors mediate sustained inhibition (Vigh, J. and von Gersdorff, H., 2005; Eggers, E. D. and Lukasiewicz, P. D., 2006) and, in the case of goldfish, generate a standing current that regulates presynaptic excitability (Hull, C. *et al.*, 2006). In the mammalian retina, feedback to the rod bipolar cell is provided by a type of wide-field amacrine cell, termed the AI or A17 amacrine cell in the cat retina (Kolb, H. and Famiglietti, E. V., 1974). The effect of this feedback has been examined by recording from the bipolar cell body before and after inhibiting GABA receptors pharmacologically, or alternatively severing the bipolar cell axon terminal (Euler, T. and Masland, R. H., 2000). These experiments imply that feedback has a powerful ability to extend the dynamic range of the bipolar cell with respect to light intensity.

It is generally agreed that feedforward from amacrine cells to ganglion cells is a powerful inhibitory pathway, but there is disagreement concerning the receptors involved. Unlike the feedback pathway, where the reciprocal rod bipolar to A17 connection has proved very useful, the lack of an anatomically identifiable pair of connected cells has hampered the study of feedforward from amacrine cells. Lukasiewicz P. D. and Shields C. R. (1998) reported that $GABA_A$ receptors alone mediate inhibition to ganglion cells of the amphibian retina, but other studies suggested that there is also $GABA_C$ and $GABA_B$ input to ganglion cells (Zhang, J. and Slaughter, M. M., 1995; Shen, W. and Slaughter, M. M., 2001). As described by Zhang J. *et al.* (1997b), there are two separate $GABA_B$ receptors on salamander ganglion cells. Both the pharmacology of these two receptors and the signaling pathways they activate are different and, though they both reduce Ca^{2+} currents, one affects an N-type Ca^{2+} channel, whereas the other affects Ca^{2+} entry through L-type Ca^{2+} channels. Clearly, Ca^{2+} entry into ganglion cell dendrites, not only through the N- and L-type Ca^{2+} channels, but also through NMDA receptors and Ca^{2+}-permeable AMPA receptors, provides a mechanism for

integrating inputs. How these mechanisms work together and what role they play in vision is not yet clear.

1.15.4 Amacrine Cell Networks

Although inhibitory interactions in the retina are often represented as simple feedback or feedforward circuits, serial synapses between amacrine processes have long been recognized (Dowling, J. E. and Boycott, B. B., 1966; Dubin, M. W., 1970) In fact, a quantitative study of the synaptic connectivity of GABAergic amacrine cells in the goldfish retina indicated that the majority of amacrine cell circuitries are relatively complex, involving nested feedback, nested feedforward, and chains of inhibition (Marc, R. E. and Liu, W., 2000).

Connections between GABAergic and glycinergic amacrines can be inferred from a simple physiological experiment that measured the effects of a glycinergic antagonist (strychnine) or a GABAergic antagonist (picrotoxin) on the light-evoked currents in retinal ganglion cells of the mud puppy. As expected, each of these antagonists reduced the inhibitory current in a majority of ganglion cells. However, the inhibitory current was enhanced in almost one-third of the ganglion cells, indicating cross-inhibition between GABAergic and glycinergic feedforward pathways (Zhang, J. *et al.*, 1997a). Thus, in a minority of ganglion cells, the glycinergic antagonist produced disinhibition of the direct GABAergic input or the GABAergic antagonist produced disinhibition of the glycinergic input; all inhibitory current was blocked by the addition of both antagonists.

1.15.5 Local Processing in Amacrine Cells

Unlike the neurons of the outer retina, amacrine cells are capable of generating action potentials that can enhance transmitter release as evidenced, for example, by the observation that tetrodotoxin applied to the retina of goldfish suppresses a large fraction of spontaneous inhibitory postsynaptic currents (IPSCs) seen in amacrine cells (Watanabe, S. *et al.*, 2000). Transmitter release, however, does not require action potentials (Gleason, E. *et al.*, 1993; 1994; Bieda, M. C. and Copenhagen, D. R., 1999), and accumulating evidence suggests that input and output are very flexibly coupled in amacrine cells.

Three related features of amacrine cells are key to understanding how these neurons work. First, the input and output synapses of amacrine cells are frequently located in close proximity on the dendrites, unlike typical neurons where the synaptic output is segregated to the axon terminal. Second, amacrine cells perform at least some of their processing functions using cytoplasmic Ca^{2+} concentrations as the computing medium, rather than membrane voltage, as is predominantly the case in typical neurons. Third, individual amacrine cells comprise multiple processing units that are more or less independent; amacrine cells can operate in different modes, with processing units tightly or loosely coupled. These three characteristics and their interactions can be illustrated with a few examples.

Commonly, the two postsynaptic elements at the ribbon synapses of bipolar cells comprise a ganglion cell dendrite and an amacrine cell dendrite. In most instances, the identities of the postsynaptic elements are unknown; but, for the mammalian rod bipolar cell, it is well established that an AII amacrine cell takes the place of a ganglion cell, with the other postsynaptic element being an AI/A17 amacrine cell (Kolb, H. and Famiglietti, E. V., 1974). As already discussed, the A17 amacrine cell is reciprocally connected to the bipolar cell terminal, but only recently it has become clear that this GABAergic feedback loop can be entirely local. A similar example of local feedback is provided by the reciprocal connection of glutamatergic mitral cells and GABAergic granule cells of the olfactory bulb (Isaacson, J. S. and Strowbridge, B. W., 1998).

When voltage-gated Ca^{2+} channels are disabled pharmacologically, the A17 process is nevertheless still able to release GABA and hyperpolarize the bipolar terminal. This is possible because the glutamate released from the rod bipolar cell opens AMPA receptors that admit sufficient Ca^{2+} to promote transmitter release from the A17 varicosity (Chavez, A. E. *et al.*, 2006). An implication of this is that transmitter release needs only modest elevations in cytoplasmic Ca^{2+} concentration, as demonstrated in cultured amacrine cells (Frerking, M. *et al.*, 1997). A mechanism analogous to that in the A17 cell holds for the feedback from amacrine cells to the goldfish MB1 bipolar cells, except that Ca^{2+} entry into the amacrine cell process is mediated through NMDA receptors (Vigh, J. and von Gersdorff, H., 2005). Transmitter release is boosted by an additional step in the A17 amacrine cell: Ca^{2+} entering through

AMPA receptors leads to calcium-induced calcium release (CICR), a process by which Ca^{2+} sequestered in the endoplasmic reticulum is liberated into the cytoplasm.

The clearest example of local dendritic processing is provided by the starburst amacrine cells (Taylor, W. R. and Vaney, D. I., 2003). These radially symmetric cells receive input from bipolar cells over the whole dendritic tree but make synaptic output to ganglion cells only from the distal dendrites. The main targets of the starburst cells are direction-selective ganglion cells (DSGCs), which respond to image motion in a preferred direction (PD) but not the opposite null direction. The key mechanism underlying the directional responses is spatially offset inhibition, which arises from starburst cells located on the null side of the DSGC but not the preferred side. Thus, for each starburst cell, processes pointing in different directions would provide the null-direction inhibition to DSGCs with different PDs (Figure 3). Moreover, patch-clamp recordings from DSGCs have shown that this inhibition is already direction selective, reflecting the direction-selective Ca^{2+} responses measured in the distal dendrites of the starburst cells (Fried, S. I. *et al.*, 2002; Euler, T. *et al.*, 2002).

Such a scheme requires that the processes of starburst dendrites pointing in one direction be functionally isolated from those processes pointing in the other directions. There is no doubt that part of this isolation reflects the electroanatomy of the starburst cell, with long thin dendrites arising from a central shunting soma (Miller, R. F. and Bloomfield, S. A. 1983). However, it also seems possible that transmitter release from starburst cells, like that from A17 cells, is not rigidly tied to membrane voltage. It is well known that the null-direction inhibition is very long-lasting and a mechanism such as CICR would be ideal for generating the appropriate temporal characteristics.

Studies on cultured amacrine cells have shown that Ca^{2+} liberated from the endoplasmic reticulum plays a significant role in transmitter release, particularly long-lasting asynchronous release. In that instance, however, Ca^{2+} release from the endoplasmic reticulum is promoted by the entry of Ca^{2+} via voltage-gated channels (Warrier, A. *et al.*, 2005) and can give rise to substantial local differences in cytoplasmic Ca^{2+} in the absence of voltage differences (Hurtado, J. *et al.*, 2002). It is clear that Ca^{2+} events in amacrine cells can occur on a wide range of spatial scales and by a variety of underlying mechanisms

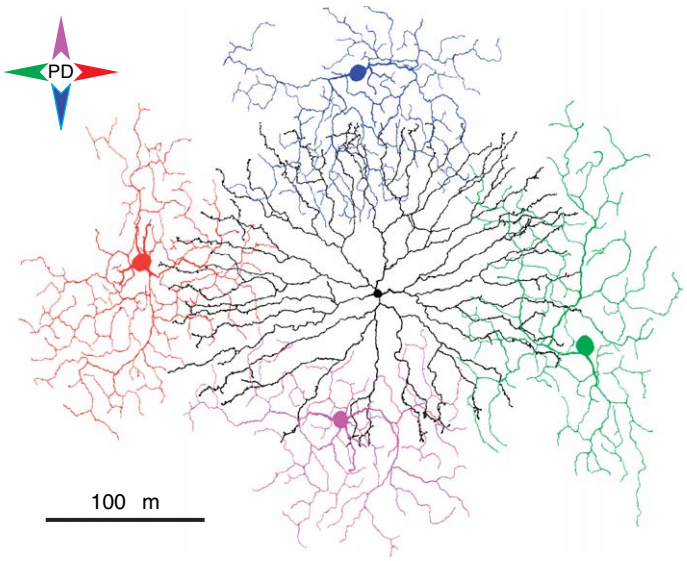

Figure 3 Local interactions of starburst amacrine cells. The rabbit retina contains four subtypes of On–Off direction-selective ganglion cells (DSGCs), whose preferred directions (PDs) are aligned with the cardinal ocular axes (colored dendritic trees and compass rose). Each DSGC receives asymmetric inhibitory input from starburst amacrine cells (black dendritic tree) located to the side of the DSGC first encountered by null-direction image motion: individual starburst cells provide null-direction inhibition to all subtypes of DSGCs. From Taylor, W. R. and Vaney, D. I. 2003. New directions in retinal research. Trends Neurosci. 26, 379–385.

(Azuma, T. *et al.*, 2004). Very likely these local and regional Ca^{2+} domains represent the dynamic functional subunits of these cells.

1.15.6 Neuromodulatory Functions

With the use of antibody staining, amacrine cells have been shown to contain a long list of peptides, such as vasointestinal peptide and substance P, that elsewhere in the nervous system are known to have roles in modulating neural function. Some amacrine cell types contain more than one peptide, for example, the enkephalin-, neurotensin-, and somatostatin-like immunoreactive (ENSLI) amacrine cells of the bird retina (Watt, C. B. *et al.*, 1985). Very little is known about the conditions under which peptides are released by amacrine cells or the function of these neuromodulators in retinal processing.

In addition to peptides, amacrine cells apparently use other signaling molecules including nitric oxide and endocannabinoids. Nitric oxide effects several distinct transient changes in the retina, including reducing the electrical coupling between horizontal cells. Studies on cultured amacrine cells have revealed an interesting and potentially important role in the inner retina: nitric oxide locally increases the cytoplasmic chloride concentration, in effect transiently converting inhibitory synapses to excitatory synapses (Hoffpauir, B. *et al.*, 2006). Recent work, also using cultured retinal neurons, has shown that endocannabinoids can increase the resting rate of transmitter release from amacrine cells (Warrier, A. and Wilson, M., 2007). Resting transmitter release is detectable in the intact retina as a continuous barrage of inhibitory input from amacrine cells (Watanabe, S. *et al.*, 2000), and it is likely that changes in the rate of resting release influence the voltage of other amacrine cells and perhaps ganglion cells.

Glossary

parvocellular or P Designates tho midget retinal ganglion cells that project to the upper four layers of the primate lateral geniculate nucleus (LGN).

magnocellular or M Designates the large retinal ganglion cells that project to the bottom two layers of the primate LGN.

Koniocellular or K* Designates those retinal ganglion cells that project to the interlaminar spaces in the primate LGN.

1.16.1 Introduction

1.16.1.1 Parallel Processing: Visual Attributes, Labeled Lines, and Neuronal Streams

The notion that the visual world is analyzed in parallel by several neuronal types goes back to Hartline's surprising discovery of ON and OFF retinal ganglion cells (RGCs) (Hartline, H. K., 1940). The discovery of the X/Y dichotomy among cat RGCs (Enroth-Cugell, C. and Robson, J. G., 1966) provided another clear example of this parallelism, and analysis of the conduction velocity of optic nerve fibers reinforced the idea further (see Stone, J., 1983). The intense interest in the magno–parvo–koniocellular groups later on (see Kaplan, E. and Shapley, R. M., 1986; Kaplan, E. *et al.*, 1990; Lee, B. B., 1996; Kaplan, E., 2003) and the anatomical studies that established the segregation of these neuronal types from the retina through the lateral geniculate nucleus (LGN) to the visual cortex (Livingstone, M. S. and Hubel, D. H., 1984a; 1984b; Shipp, S. and Zeki, S., 1985; Livingstone, M. and Hubel, D., 1988) have all added further weight to the view that the world is being analyzed in parallel by several streams, and this hypothesis has become widespread in the visual neuroscience literature (e.g., Ungerleider, L. G. and Mishkin, M., 1982; Livingstone, M. and Hubel, D., 1988; Zeki, S., 1993; Callaway, E. M., 2005).

Visual attributes. In the physical world we find only space and time. Vision scientists, however, commonly organize the various combinations of spatiotemporal properties of the visual world into concepts such as color, size, motion, orientation, and texture. It is very tempting then to imagine that each aspect of the visual world is dealt with by a specialized neuronal population that is dedicated to the analysis of one (or a few) of these aspects of the visual environment: color and other surface properties could be scrutinized by the tonic, high-resolution parvocellular stream, motion could be detected and analyzed by the phasic, coarse magnocellular stream, and so forth. We must remember, however, that these organizing concepts are a figment of the vision scientist's imagination, and that – at this point – their existence or representation in the brain in any specific form is merely a hypothesis. We shall return to this issue later.

1.16.1.2 Classification of Cells into Types

An important first step in any scientific endeavor is to classify the objects under scrutiny, and then try to deduce from the properties of the different classes something about the role that they play in the system under study. The classification of neurons into various groups takes into account various aspects: morphology, connectivity, neurochemistry, and physiological properties, such as the spatial and dynamical properties of their receptive field (for visual neurons). Sometimes neurons are divided into classes along one dimension only, such as transient–sustained, simple–complex, or ON–OFF, and some properties tend to cluster together. For example, transient cells are large, ON cells synapse in a particular sublamina of the inner plexiform layer. Such clustering of properties often provides seductive hints about the possible role that a given population might play in the overall function of the system. For more information regarding classification criteria, and more references concerning cell typing and classification, see Rodieck R. W. and Brening R. K. (1983) and Troy J. and Shou J. (2002).

1.16.2 Properties of the M, P, and K Streams

Comprehensive comparisons of the properties of the three main streams (magnocellular, parvocellular, and koniocellular) can be found in Kaplan E. *et al.* (1990) and Kaplan E. (2003). The presentation here will therefore be brief, and we shall discuss the retina and LGN together. Our current knowledge of the various properties is summarized in Table 1.

1.16.2.1 Anatomy

1.16.2.1.1 Numbers, density, and resolution

Numbers. By far, the majority of the RGCs in the primate retina (~80%) are midget (Polyak, S. L., 1941) cells, which project to the parvocellular (upper four) layers of the LGN of primates (Goodchild, A. *et al.*, 1996). Because of their projection target, they are referred to as P cells. The much larger parasol (Polyak, S. L., 1941) cells project to the magnocellular (bottom two) layers of the LGN, and are thus called M cells. They account for ~10% of the RGCs (Leventhal, A. G. *et al.*, 1981; Perry, V. H. and Cowey, A., 1984). A population of small (but not midget) bistratified blue ON ganglion cells projects to the koniocellular layers, the thin interlaminar zones between the major layers of the LGN (Dacey, D. M. and Lee, B. B., 1994). In the LGN, the

Table 1 Properties of the P, M, and K neuronal streams

	Property	*P*	*M*	*K*
1	Clear spectral opponency	Yes (red-green)	No	Some (blue-yellow)
2	Response to light steps	Tonic	Phasic (transient)	Phasic; some sluggish
3	Luminance contrast gain	Low	High	Diverse (some high)
4	Receptive field size	Small	Large	Large
5	Spatial resolution of individual neurons	Similar to M	Similar to P	Diverse (some like M)
6	Retinal ganglion cell density (acuity of cell group)	High	Low	?
7	Retinal source	Midget RGCs	Parasol RGCs	Unknown (some blue-ON bistratified RGCs)
8	LGN projection target	Parvocellular	Magnocellular	Koniocellular (intercalated) layers
9	V1 projection target	Layer 4Cβ	Layer 4Cα	Layers 2–3, CO blobs, layer 1
10	Cell body size	Small	Large	Large/varied
11	Conduction velocity of retinal axons	Medium	High	Low/varied
12	Contrast sensitivity at scotopic luminance	Poor	Good	?
13	Linearity of spatial summation	Linear (X-like)	75% Linear, 25% Nonlinear (Y-like)	Linear (X-like)
14	Extraclassical receptive field effects	Weak	Strong	Intermediate (varied)
15	Number of cells (fraction of LGN population)	~1 000 000 (85%)	~70 000 (6%)	~100 000 (9%)

koniocellular cells comprise ~9% of the nucleus' population (Hendry, S. H. C. and Yoshioka, T., 1994; Hendry, S. H. C. and Reid, C. R., 2000). It is likely that other types of ganglion cells also project to the koniocellular layers, but these have not been identified yet.

Density and resolution. Although it was initially thought that the ratio of M and P RGCs varies with retinal eccentricity, more recent data indicated that the ratio remains essentially constant throughout the retina (Perry, V. H. and Cowey, A., 1984; Silveira, L. C. L. and Perry, V., 1991). Since the P cells are much more numerous and close to each other, the resolution with which they sample visual space is higher than that available to the more sparse M or bistratified cells. We note, however, that the greater contrast sensitivity of M cells (Contrast Gain) allows them to detect fine patterns (Blakemore, C. and Vital-Durand, F., 1986; Crook, J. M. *et al.*, 1988), although their sparse coverage of the retina prevents them from providing enough information for the identification of such patterns.

1.16.2.1.2 Size

On average, the receptive field diameters of M cells at all retinal eccentricities are approximately 2.5–3 times as large as those of P cells, which makes their receptive field area roughly 6–8 times larger (Croner, L. J. and Kaplan, E., 1995). This size advantage is responsible in large part for their increased sensitivity to luminance contrast (Kaplan, E. and Shapley, R. M., 1986, Contrast Gain). The link between size and contrast sensitivity (Enroth-Cugell, C. and Shapley, R. M., 1973b) is also seen in K cells. For example, the K cells in the LGN of owl monkeys are approximately as large as the M cells, and their contrast sensitivities are similar as well (Xu, X. *et al.*, 2001).

1.16.2.1.3 Connectivity: inputs and projections

Retina. The midget (P) cells receive their input from midget bipolar cells. Near the fovea, this input is private: each ganglion cell receives input from one bipolar cell, which, in turn, is driven by a single cone. This arrangement is required for maximal spatial resolution, and the resulting improved color-analyzing mechanism could be a beneficial by-product. Farther from the fovea, the dendritic trees become larger, and the midget cells receive input from several cones, reducing their chromatic selectivity. The parasol (M) cells receive input from diffuse bipolars (Boycott, B. B. and Wässle, H., 1991),

which collect input from several different cones, making them more sensitive but less suitable for chromatic analysis. The small bistratified cells receive their input from bipolars that synapse at both the upper and the lower portions of the inner plexiform layer, and their receptive field centers are driven by S (blue sensitive) cones (Dacey, D. M. and Lee, B. B., 1994).

LGN and V1. The main groups of RGCs project to distinct layers or compartments in the LGN and in V1. The four parvocellular layers of the LGN receive their input from the midget RGCs (P cells), but also from other ganglion cell types, including some with very large dendritic trees (Rodieck, R. W. and Watanabe, M., 1993). They project to layer 4Cβ of the primary visual cortex, V1. The two lower layers of the LGN (magnocellular) receive their input from the parasol cells, and project to layer 4Cα of V1. The koniocellular layers receive input from the small bistratified (blue ON) cells, and project directly to the cytochrome oxidase blobs found in layers 2 and 3 of V1 (Hendry, S. H. C. and Yoshioka, T., 1994; Yabuta, N. H. and Callaway, E. M., 1998a; 1998b).

Beyond V1. From V1 the various neuronal streams project to numerous higher brain areas (Felleman, D. J. and van Essen, D. C., 1991; Kaplan, E., 2003). The overall pattern of these projections stimulated the suggestion that they form two main functional streams, one (dorsal) that answers the question 'Where?', and the other (ventral) to explore 'What?' is out there (Ungerleider, L. G. and Mishkin, M., 1982). This theory combines a hierarchical flow of information with the notion of parallel processing of various visual attributes, and is in wide circulation today. As we shall argue below, the broad acceptance of its simplistic form rests on somewhat shaky ground, and is perhaps premature.

1.16.2.2 Physiology

Many of the physiological properties such as contrast gain, receptive field size, center-surround antagonism, and chromatic selectivity are directly related to the morphological properties reviewed above, and appear to be determined by the early circuitry of the outer retina (Dacey, D. *et al.*, 2000). Other properties, such as dynamics, are related to both the connectivity pattern and the biophysical repertoire (including ion channels, neurotransmitters, and receptors) of the neurons.

1.16.2.2.1 Dynamics

The difference between the temporal properties of M cells and those of P cells (Gouras, P., 1968) was the first physiological indication that the primate retina contains more than one homogeneous population of RGCs, something that the anatomists have known for some time. Gouras P. (1968) reported that the discharges of some RGCs were phasic, while others fired tonically. At the time, the projection pattern of these cells to the LGN layers was unknown, and only later it was determined that the phasic cells correspond to the anatomical cell type called parasol cells, which were found to project to the magnocellular layers of the LGN, while the tonic cells correspond to the midget RGCs, which project to the parvocellular layers of the LGN (Leventhal, A. G. *et al.*, 1981). Further study of the dynamical properties and the linearity of their temporal responses has shown that both M and P cells have nonlinear response properties, although these are more pronounced in the M population (Kaplan, E. and Shapley, R. M., 1989; Benardete, E. A. and Kaplan, E., 1997; 1999).

The fact that M cells are much more phasic than P cells has led to the hypothesis that they are specialized for the detection and analysis of motion, while the tonic P cells are thought to be used for the analysis of surface properties.

1.16.2.2.2 Linearity of spatial summation; X–Y

In the cat, Y RGCs are larger and more phasic than X cells (Enroth-Cugell, C. and Robson, J. G., 1966), and it was tempting to seek a homology between the X–Y classes of the cat retina and the P–M types in the primate retina (Dreher, B. *et al.*, 1976; Sherman, S. M. *et al.*, 1976). However, the initial attempts did not use the original classification approach that was used in the cat by Enroth-Cugell and Robson, who called X cells those cells that showed linear spatial summation within their receptive fields. When that same criterion was used, all P and most M cells turned out to be rather like cat X cells, and only a minority of M cells had significant nonlinear spatial summation (Kaplan, E. and Shapley, R., 1982; Levitt, J. B. *et al.*, 2001). We note that such a homology contributes little to any compelling determination of the role that these cell classes play in primate vision. It is reasonable, however, to postulate that the P/midget system is a later evolutionary specialization found in monkeys but not in cats.

1.16.2.2.3 Chromatic properties

P cells. The retinal connectivity pattern of these cells, which, near the fovea, provides each one with a private line from a single cone, endows them with both high spatial resolution and chromatic selectivity. The center region of the receptive field is obviously tuned to the same wavelength that the central cone prefers. Much controversy surrounded the chromatic selectivity of the surround mechanism of P cells' receptive fields. Early reports suggested that the surround of many P cells receives specific input from cones that are tuned to a wavelength different from that to which the center is tuned (Wiesel, T. N. and Hubel, D. H., 1966; De Monasterio, F. M. and Gouras, P., 1975), and the cells typically fall into one of two major groups: r-g and b-y cells (Derrington, A. M. *et al*., 1984). However, anatomical studies have shown that the horizontal cells, widely believed to mediate the surround response, receive promiscuous, nonspecific cone input (Boycott, B. B. *et al*., 1987). Further physiological measurements have demonstrated that for most of the P cells (and their recipient parvocellular LGN targets), the input to the surround is, functionally, rather selective (Reid, R. C. and Shapley, R. M., 1992). It is possible, in principle, that this chromatic selectivity is accomplished through some processing in the inner plexiform layer, but a detailed anatomical study of this possibility has failed to support it (Calkins, D. J. and Sterling, P., 1996). Thus the anatomical substrate for the chromatic selectivity of the surround of near-foveal P cells remains elusive. We note, however, that even a mixed cone input to the surround can still provide robust color vision capabilities (Paulus, W. and Kröger-Paulus, A., 1983; Lennie, P. *et al*., 1991).

M cells. Most of these cells receive combined L and M cone input to both center and surround of their receptive fields, with little contribution from S cones (Wiesel, T. N. and Hubel, D. H., 1966; Lee, B. B. *et al*., 1989). Other studies have found the magnocellular portion of the LGN to be both spatially and chromatically antagonistic (Derrington, A. M. *et al*., 1984). In a few magnocellular cells, the surround receives inhibitory input from L cones (Wiesel, T. N. and Hubel, D. H., 1966). The broad-band, nonselective nature of the responses of M cells motivated the suggestion that they are responsible for the color-blind luminance channel of psychophysics.

K cells. Some of these LGN cells have been shown to receive input from the small bistratified RGCs, which receive their excitatory input from S cones (Dacey, D. M. and Lee, B. B., 1994). They thus provide the cellular substrate for the blue ON channel. The chromatic properties of the other cells that project to the koniocellular layers of the LGN remain to be elucidated.

It appears that the major factor that determines the chromatic properties of the P, M, and K cells is the spatial characteristics of their receptive fields, rather than any specialized, genetically directed selectivity in the connectivity pattern between cones and ganglion cells. Evidence in support of this conclusion comes also from comparative studies (see, e.g., Yamada, E. S. *et al*., 1998; Blessing, E. *et al*., 2004).

1.16.2.2.4 Contrast gain

Contrast gain is the relative change in response for a given change in stimulus contrast. It is related to the size of the light collecting pool of the receptive field (Enroth-Cugell, C. and Shapley, R. M., 1973a; Croner, L. J. and Kaplan, E., 1995; Troy, J. and Shou, T., 2002; Blessing, E. *et al*., 2004), which, incidentally, also determines the light adaptation state of the cell, and thus its dynamics as well (Enroth-Cugell, C. and Shapley, R. M., 1973b). Since at any retinal eccentricity M cells are larger than P cells, their contrast gain to luminance stimuli is typically higher than that of the P cells around them (Kaplan, E. and Shapley, R. M., 1986; Croner, L. J. and Kaplan, E., 1995). This is especially true for low-contrast stimuli. At higher contrasts, the M cells' response increases at a rate that is rather similar to that of P cells (Figure 1).

The similar contrast gain of P and M cells at high contrasts suggests the possibility that in P cells there is only one mechanism that is responsible for the response, while in M cells two mechanisms are at work: one operates at low contrasts, and once that mechanism saturates (at intermediate contrasts), another mechanism, which might be common to both M and P cells, takes over. It is therefore unlikely that the contribution of the magnocellular population disappears at high contrasts (Rudvin, I. *et al*., 2000), because M cells continue to increase their response up to 100% contrast (Figure 1).

K cells tend to be more like M cells in several respects, including their contrast gain (Xu, X. *et al*., 2001). Note, however, that not only size but the number of input synapses and other factors can also influence contrast gain (Croner, L. J. and Kaplan, E., 1995).

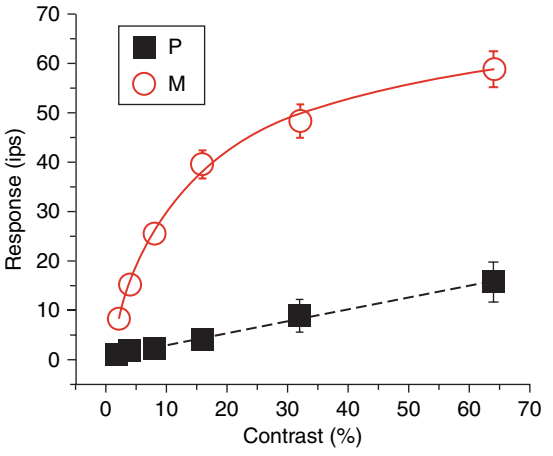

Figure 1 The contrast gain of M cells is higher than that of P cells for luminance stimuli. Shown are average responses of 28 P and 8 M retinal ganglion cells from one rhesus monkey as a function of luminance contrast. The stimulus was a drifting black-white sine wave grating of optimal spatial frequency for each cell, which modulated each cathode ray tube (CRT) pixel at 4 Hz. The smooth curves are the Michaelis–Menten equation, $y = ax/(b + x)$; error bars: ± 1 SEM. The half-saturation value, b, for the M (magnocellular projecting) ganglion cells, was 14%. Note the steeper slope (higher gain) at low contrasts for M cells (after Kaplan, E. and Shapley, R. M., 1986).

1.16.2.2.5 Spatial resolution

The high contrast gain of M cells is due, primarily, to their large receptive field. Because of their size, their density is low, and therefore they sample visual space rather sparely, which makes it impossible for them to identify fine patterns. Thus individual M cells can detect a fine drifting grating (Blakemore, C. and Vital-Durand, F., 1986; Crook, J. M. *et al.*, 1988), but the M system cannot determine whether it is drifting up or down. Despite their coarseness, the greater signal-to-noise ratio of M cell discharge suggests that they might contribute to hyperacuity performance (Rüttiger, L. and Lee, B., 2000; Rüttiger, L. *et al.*, 2002; Sun, H. *et al.*, 2004). For further details, see Kaplan E. (2003).

1.16.2.2.6 Extraclassical receptive field

We have detailed information about the classical receptive field (as originally defined for visual neurons by H. K. Hartline) of neurons in the early visual system of primates (for a review, see Kaplan, E., 1991). However, it is known that the response to a visual stimulus can be influenced by stimuli that fall far beyond that classical receptive field (see, e.g., Krüger, J., 1977). This is true for RGCs, LGN cells, and V1 neurons. The neural basis of these nonlinear effects is not firmly established, beyond the suspicion that, in the retina, amacrine cells are involved in mediating them. These effects have been investigated more completely in the New World primate, the common marmoset, than in the Old World primates like macaques (Felisberti, F. and Derrington, A., 2001; Solomon, S. G. *et al.*, 2002; Webb, B. S. *et al.*, 2002). In marmoset the nonclassical receptive field effects are mostly suppressive, and are more pronounced in the magnocellular layers of the LGN than in either parvocellular or koniocellular layers. The greater sensitivity of magnocellular neurons to stimulation beyond the classical receptive field was reported also by Felisberti F. and Derrington A. (2001) and by Webb B. S. *et al.* (2002), and might be related to the greater abundance of inhibitory interneurons in the magnocellular layers, compared with the parvocellular layers (Hámori, J. *et al.*, 1983). These findings suggest that cortical neurons might inherit much of their nonclassical receptive field properties from their subcortical inputs (see also Bonin, V. *et al.*, 2005).

1.16.2.3 Summary: The Properties of the Three Neuronal Streams

Table 1 summarizes the state of our current knowledge of the anatomical and physiological properties of the three main neuronal streams of the early primate visual system. Clearly, there are gaps in this summary view, and some of these gaps and their implications are taken up in the next section. Nevertheless, the clustering of properties listed in Table 1 has led to the hypothesis that links each of the three major streams to some distinct perceptual functions (Table 2). In the next section, we examine the validity of this hypothesis.

Table 2 The representation of the outside world in mind and brain

The visual world	*The mind's eye*	*The brain*
	Luminance	M?
	Motion, flicker	M,K?
	Hyperacuity, vernier	M?
$f(x, y, t, I, \lambda)$	Size	P,K?
	Color	P,K?
	Orientation	P?
	Texture	P,K?
	Depth	P?
	…	–
	…	–

The function in the left column describes the spatiotemporal distribution of light across the retina. x, y are retinal coordinates, t is time, I is intensity, and λ is wavelength.

1.16.3 How Solid Is the Parallel Streams Hypothesis?

Having briefly summarized the properties of the three major neuronal streams in the primate visual system (Table 1), and the prevalent view, which postulates a close, one-to-one correspondence between these streams and certain visual functions, we now raise some questions about the validity of such a view. This discussion should be viewed as a critical evaluation of the quality of the evidence in favor of the parallel streams hypothesis, the philosophical and psychological motivation for accepting it, and the possibility that some other design might be at work in the brain.

We note that the validity of the prevalent view is not only of purely academic interest, because, in addition to stimulating and directing many investigations of the brain and influencing the interpretation of experimental results, it has also inspired numerous computational models and simulations (e.g., Takács, B. *et al*., 1994; van Essen, D. and Andreson, C., 1995), and had a strong influence on machine vision.

1.16.3.1 The World, the Mind, and the Brain: The Siren Lure of Parallel Functional Streams

In the physical world, only space and time need to be specified in the description of any visual object or process (it is usually helpful to add wavelength and intensity as well). Vision scientists, however, typically organize the various manifestations of the visual world into certain visual attributes, such as color, motion, size, orientation, and texture. The extraction of each of these attributes from the spatiotemporal light distribution across the photoreceptor mosaic requires some neural computation and filtering. Conceptually, these attributes, which originated in psychological research on visual perception, can be viewed as similar to quantities such as pressure or heat in physics, which serve as shorthand global descriptions of the state of multitudes of atoms or molecules. The distinction between the physical, primary properties (left column of Table 2), and the perceptual, secondary properties (middle column of Table 2), is like the one made by John Locke in his *Essay Concerning Human Understanding* (1690).

From a belief in such a perceptual organization (of the secondary properties) it is but a small tempting step to assume that the brain organizes visual information in a similar fashion, and this assumption naturally leads to a search inside the brain for the physical footprints of these visual attributes. Vision scientists thus look for the neural representations of color, orientation, size, and motion in the brain. This quest often takes the form of a search for the brain area or neuronal population that is devoted to the analysis of a particular visual attribute. The three parallel domains of the physical, perceptual, and neuronal worlds are depicted schematically in Table 2.

We should bear in mind, however, that any notion of a specific organization of physical quantities into perceptual qualities is merely a theory. The association of distinct, segregated neuronal streams or populations with specific functional roles is, likewise, a (optional and inessential) corollary of the theory. Even if the world were, indeed, represented in our mind's eye along the dimensions of color, size, motion, etc., this representation could, in principle, be distributed across the neuronal network that comprises the visual system, and not lumped into functionally specific anatomical clusters or compartments. In addition, the attributes need not be represented by labeled lines or populations, but rather by the coordinated dynamical activity or temporal discharge patterns of the network. In other words, the representation of physical quantities in the brain need not be based on anatomy (cell location and connectivity) alone.

Economy of wires. An important advantage of clustering according to function is that, if extensive information exchange among members of a cluster is required (another hypothesis), clustering will reduce the length of the neuronal processes that will need to be created and maintained at high costs. Keeping the wires short has thus emerged as an important, perhaps even crucial, selective pressure on nervous systems (Mead, C., 1989; Cherniak, C., 1992; 1994; Chklovskii, D., 2000). Note, however, that we do not know what computational imperatives require interaction among functionally similar neurons, although some suggestions have been made (e.g., Somers, D. C. *et al*., 1995; Xiao, Y. *et al*., 2003).

1.16.3.2 Challenges to the Parallel Streams Hypothesis

We shall now sketch several reasons why the association of some neuronal populations with specific perceptual functions should be viewed with some caution. The argument rests on anatomical, physiological, and psychophysical findings. This sketch is

certainly incomplete at this time, and much work will be required to fill in the gaps in it.

1.16.3.2.1 Criteria for the validity of the parallel streams hypothesis

For a strict correspondence between distinct (anatomical) parts of the visual system and visual functions to hold, certain minimal criteria must be met:

1. *Homogeneity.* Each neuronal population that performs a distinct function should be homogeneous.
2. *Stream Isolation.* There should be no communication among the various parts that perform distinct functions.
3. *Perceptual Independence.* The perceptual functions should be distinct and independent of each other.
4. *Compatibility.* The properties of the neurons in each part should match the perceptual function that it is supposed to perform.

Note again that the parts (neuronal populations or streams) need not be physically segregated – functionally different neuronal clusters could, in principle, be mixed together, although such mixing could incur a high metabolic cost, because it is likely to increase the length of the nerve fibers in the brain.

As we shall see below, these criteria are not quite met by either the M, P, and K neuronal streams or the perceptual functions they are supposed to support.

1.16.3.2.2 How homogeneous are the Three neuronal types?

At the root of the proposed correlation between neuronal types and perceptual functions is the assumption that each neuronal population is relatively homogenous, at least along some dimension (our first criterion), and that most such types cover the entire visual space, in order to support the proposed function everywhere in the visual field. However, a simple one-to-one correspondence between perceptual tasks and neuronal types is impossible, since there are more perceptual aspects to cover than could be accounted for by the three main types that we have been discussing. This suggests that each group might have to take care of more than one perceptual task, perhaps by some specialized subtypes. The discovery of the koniocellular population (Hendry, S. H. C. and Yoshioka, T., 1994) and the melanopsin-containing RGCs (Berson, D., 2003) are but two recent examples of neuronal populations that were overlooked and were unknown in early studies (see also Watanabe, M. and Rodieck, R. W., 1989; Peterson, B. and Dacey, D., 1998; 1999; 2000; Calkins, D. *et al.*, 2005). How many more neuronal groups are awaiting discovery is unknown, and a function–structure correlation should probably wait until most of the distinct neuronal types have been described.

1.16.3.2.3 Anatomy

Several types of anatomical arguments provide reasons to reevaluate the prevalent view:

1. *Are there enough cell types for all the perceptual tasks?* The three major types in Table 1 are defined by (and derive their names from) the location of their cell bodies in the various compartments of the primate LGN. However, the RGCs that excite them are not monolithic types. The M cells come in at least two flavors: those that receive some amacrine input and those that receive three times as much amacrine input (Calkins, D. *et al.*, 1995). Note, however, that it is not yet established whether the different amount of amacrine input is related to the different degree of nonlinearity observed among M cells (Kaplan, E. and Shapley, R., 1982; Demb, J. *et al.*, 1999). The ganglion cells that project to the parvocellular layers also comprise several anatomical subtypes, some with tiny (midgets) and other with very large dendritic trees (Watanabe, M. and Rodieck, R. W., 1989), suggesting that they participate in diverse visual functions. Less is known about the koniocellular population, but it is likely that the blue-yellow bistratified cells that project to the K layers are not the only ganglion cells to do so. Further research will probably discover other types. We should also allow for the possibility that specialized subnetworks, distinguished primarily by their connectivity patterns rather than by their cell type, support various aspects of some perceptual tasks. Anatomical data in support of such a possibility have been reported recently for the visual cortex (Yoshimura, Y. *et al.*, 2005).
2. *Crosstalk among streams.* A different sort of argument against the simple correlation between neuronal types and visual function comes from anatomical evidence for crosstalk among the various streams (Malach, R., 1994; Malach, R. *et al.*, 1994; Sincich, L. and Horton, J., 2002; 2003; 2005). These anatomical connections violate our second required criterion, and they are likely to contribute to crosstalk among perceptual functions (see below).
3. *Lesion studies.* Some of the evidence for the hypothesis of separate functional streams comes from lesion studies, either on humans (Ungerleider, L.

G. and Mishkin, M., 1982) or on monkeys (Eskin, T. A. and Merigan, W. H., 1986; Merigan, W. H. and Maunsell, J. R. H., 1990; Logothetis, N. K. *et al.*, 1990; Merigan, W. H. and Maunsell, J. R. H., 1993). The interpretation of lesion studies suffers from both technical and conceptual difficulties. It is always difficult to be certain that the lesion is complete and specific, especially in human studies. In addition, examining the behavior or physiology of a lesioned brain can tell us not what the lesioned area does, but rather what the system can (or cannot) do without the missing area. These considerations reduce the weight that can be given to lesion-based evidence.

More specific arguments, based on detailed analysis of anatomical connections, and especially the relationship between the V1 to V2 pattern and the cytochrome oxidase compartments of V2 can be found in Horton J. and Sincich L. (2004) and Sincich L. and Horton J. (2005).

1.16.3.2.4 Physiology

The physiological literature contains several findings that pose difficulties for the parallel streams view. Below are a few examples:

1. In many brain areas, and especially in V1, most neurons are tuned to several stimulus parameters, although the tuning sharpness varies. This indicates that the neuronal discharge is modulated typically by more than one stimulus parameter at any given moment.
2. The proportion of cells in any given cortical (visual) area that are devoted exclusively to the presumed function of the area vary greatly among studies (Felleman, D. J. and van Essen, D. C., 1987). For example, in area V4, which is supposed to be the color area of the 'what?' stream (Shipp, S. and Zeki, S., 1985), only $\sim$ 20% of the cells show color selectivity or color opponency, on par with other cortical areas (Schein, S. J. *et al.*, 1982; Felleman, D. J. and van Essen, D. C., 1987).
3. Interactions between motion and chromatic signals have been documented in neurons of the macaque middle temporal area (MT), a cortical area that is believed to be dominated by M input (Dobkins, K. R. and Albright, T. D., 1994), and in magnetoencephalograhic (MEG) recordings from humans (Amano, K. *et al.*, 2004).
4. M cells have varying degrees of nonlinear spatial summation (Kaplan, E. and Shapley, R., 1982), perhaps representing the amount of amacrine synaptic input that they receive.

1.16.3.2.5 Psychophysics

The notion of segregation of function implies that the sensitivity for a given visual attribute should not be affected by the values or modulation of other attributes. For instance, color should be independent of luminance, or of the orientation or motion of the stimulus. However, despite initial reports that suggested perceptual segregation (e.g., Livingstone, M. S. and Hubel, D. H., 1987), there are now numerous psychophysical results that document significant interactions among these attributes (see, e.g., Switkes, E. *et al.*, 1988; Krauskopf, J. and Farell, B., 1990; Stoner, G. R. *et al.*, 1990; Cavanagh, P. and Anstis, S., 1991; Kooi, F. L. and De Valois, K. K., 1992; Sinha, P., 1995; Gegenfurtner, K. and Hawken, M., 1996; Nijhawan, R., 1997; Yantis, S. and Nakama, T., 1998; Giese, M., 1999; Clifford, C. W. G. *et al.*, 2003; Shabana, N. *et al.*, 2003).

In a way analogous to our previous argument regarding the heterogeneity of anatomical or physiological groupings, there is also evidence that (at least some) perceptual functions are not monolithic, and that they, too, depend on the interplay among several mechanisms (Gegenfurtner, K. and Hawken, M., 1996; Stockman, A. and Plummer, D., 2005). Thus it is unlikely that any of these complex functions is performed by a single neuronal population.

It is not known currently whether the interactions mentioned above are due to direct interactions among the various neuronal types/streams, or to top-down influences of the massive descending pathways that are ubiquitous in the brain, but it is likely that both contribute to the mutual influences among both streams and perceptual functions.

1.16.3.3 The Need for Alternative Theories

Our discussion here suggests that the experimental results in the literature do not yet provide sufficient constraints for the construction of a coherent view of how the outside world is represented in our brains, and, in particular, how visual objects are recognized by the combination of their visual attributes. It is clear that more experiments alone will not help. What we need are bolder theoretical approaches, anchored in the anatomy and physiology of the brain, but with sufficient distance from current views to allow for a fresh perspective. It is likely that computational simulations of large neuronal ensembles and circuits, of the

types that are beginning to emerge (McLaughlin, D. *et al.*, 2000; Omurtag, A. *et al.*, 2000a; 2000b; Giles, J., 2005), will play an important role in this quest.

1.16.3.3.1 Labeled lines, multiplexing, dynamical networks, and the modularity of functional organization

It is important to keep in mind the essential distinction between the notions of labeled lines and the anatomical clustering of cells according to the properties of their receptive fields. The two are, in principle, independent of one another: cells that perform a particular function may, or may not, cluster together in a given compartment or brain region. The ideas discussed above do not require or imply any connection between these two concepts.

The notion of labeled lines with distinct visual functions implies that the neurons in any given line will be tuned to only one visual parameter: color, orientation, speed of motion, etc. That means that if we modulate a stimulus along one dimension (say, change only its color), some neuronal population will respond, while others will ignore the modulation. However, as we noted above, the literature paints a different picture: most cortical neurons are tuned to many parameters, which means that most neurons will respond to most types of modulations (albeit to different degrees), and their discharge will therefore be ambiguous, because different combinations of stimulus parameters will produce similar firing rates or patterns. Interpreting the discharge pattern of the population, therefore, requires a coordinated computation that involves many neurons.

A heavily interconnected dynamical network like the brain might implement several distinct strategies to accomplish the tasks it faces. It is reasonable to assume that these strategies will depend on the task at hand, and therefore it could be that different functions rely on different strategies: in some cases, labeled lines and clustering might be advantageous, while in others, temporal discharge patterns could be more important (for a review, see Victor, J. D., 1999). Clearly, combinations of these, and other mechanisms, could be employed as well.

In the visual system there is a crucial factor that must be taken into account: the topographical representation of the world in the brain (Tootell, R. B. H. *et al.*, 1982). The topographic map forces the creation of cortical regions (hypercolumns) that must contain all the neuronal machinery that is required to handle whatever a region of visual space might present.

This means that all the streams should exist in each piece of cortex that represents a point in space. This mapping suggests that local interactions are, indeed, important in the visual cortex, and are probably responsible for the modular nature of the functional architecture of the cortex.

1.16.4 Conclusions

I have presented the prevalent view of a close correspondence between the major anatomical streams and visual functions, and raised some questions regarding the validity of such a theory. It is too early to present a coherent alternative to the parallel streams hypothesis. It might well be that further research will uncover a sufficiently large number of neuronal streams, each with exquisite selectivity for one or a few visual parameters. Many of the issues raised here could be settled by such a development, and the final picture will be similar, in principle, to the current three-way view, but with many more streams.

It is also possible that a deeper understanding of the temporal patterns of neuronal discharge across neural populations will reveal new ways in which the brain represents, encodes, and transforms physical attributes or their combinations. This means that neurons could, in principle, process different sorts of information at different times, depending on the context and the stimulus (see, e.g., Basole, A. *et al.*, 2003). Obviously, we should not ignore the clear differences among the neuronal types (Table 1). Discovering how these differences are employed in support of visual function remains a challenge. The future, no doubt, will continue to be exciting and surprising.

Glossary

first-order statistics Mean luminance or contrast.

Gabor wavelet An oriented filter that is bandpass in both space and spatial frequency, similar in profile to a Gaussian-modulated sine wave.

higher-order statistics Statistical properties beyond second order. These are described by the Fourier phase spectrum rather than the amplitude spectrum.

information exploitation A theory that proposes the visual system should exploit signals that reliably indicate which structural elements are present in a scene.

natural image An image whose statistical properties (i.e., the distributions and joint distributions of pixel luminances) are representative of those encountered during natural vision.

natural scene See natural image.

redundancy reduction A theory that proposes the visual system should tend to ignore or reduce the influence of noninformative or redundant signals in the environment.

second-order statistics The Fourier amplitude or power spectrum.

sparse representation A set of filters designed so that a relatively small number of them is required to encode any specific natural image.

The ultimate purpose of the visual system is to create a useful internal representation of the complex, cluttered scenes that occur in the natural world. To solve this difficult computational problem humans and other primates have evolved a sophisticated visual system that consists of numerous distinct areas, embedded within a complex hierarchical and parallel network (Van Essen, D. C. and Gallant, J. L., 1994; Tootell, R. B. H. *et al.*, 2003). At the level of the peripheral photoreceptors natural images are represented as discretely sampled spatial images that vary continuously in time. Although these retinal images contain a vast amount of information about the external scene, most of this information is only implicit and cannot be extracted directly from the samples. At each successive stage of visual processing, each visual area performs a transformation that renders explicit some of the information represented only implicitly in the retinal image.

It has been argued that a maximally efficient visual system (i.e., one that minimizes computational load) should follow two general principles (Attneave, F., 1954; Laughlin, S., 1981; Atick, J. J. *et al.*, 1992; van Hateren, J. H., 1992; Field, D. J., 1994; Rieke, F. *et al.*, 1995; Zetzsche, C. and Krieger, G., 1999; Barlow, H. B., 2001). First, the visual system should tend to ignore or reduce the influence of noninformative or redundant signals in the environment (redundancy reduction). Second, the system should exploit signals that reliably indicate which structural elements are present in a scene (information exploitation). Given the hierarchical organization of the visual system, it

seems likely that peripheral stages focus most on relatively simple statistical stimulus properties, and more central stages focus on higher-order statistical regularities that are more difficult to extract from natural images. Even so, it is likely that each processing stage probably involves both redundancy reduction and signal exploitation.

The complimentary principles of redundancy reduction and signal exploitation suggest a potentially valuable and interesting strategy for investigating the visual system based on explicit consideration of the statistical structure of natural scenes (Field, D. J., 1993; 1994; Simoncelli, E. P. and Olshausen, B. A., 2001). Statistical regularities in natural images can be used as the basis for computational theories of optimal visual processing (Foldiak, P., 1990; Atick, J. J. *et al.*, 1992; Olshausen, B. A. and Field, D. J., 1996; Bell, A. J. and Sejnowski, T. J., 1997; van Hateren, J. H. and van der Schaaf, A., 1998; Simoncelli, E. P. and Schwartz, O., 1998); they can be used to test and interpret various theories of human vision (Dan, Y. *et al.*, 1996; Vinje, W. E. and Gallant, J. L., 2000; Sharpee, T. O. *et al.*, 2006); and they can be used as a powerful tool for investigating aspects of visual function about which little is currently known (David, S. V. *et al.*, 2006).

1.17.1 What Is a Natural Scene?

Researchers often distinguish between natural images and other stimuli that are not natural (e.g., sinusoidal gratings, white noise, etc.; Carandini, M. *et al.*, 2005; Rust, N. C. and Movshon, J. A., 2005). However, these two types of stimuli actually represent points on a continuum rather than discrete classes. Any image is natural to the extent that its statistical properties (i.e., the distributions and joint distributions of pixel luminances) are generated by the scenes we commonly encounter during natural vision (Field, D. J., 1987). According to this criterion some images, such as forests or meadows, are very natural; others, such as gratings or white noise, are relatively unnatural; still others, such as a cityscape or an interior scene, likely fall between these two extremes. Note that even the most unnatural scenes have some probability of appearing in the natural world. For example, one might acquire an image of a sinusoidal grating or white noise pattern while taking close-up photos of natural textured surfaces.

An understanding of the statistical properties of natural images and how the visual system exploits them provides insight into the function of known neural mechanisms and we can potentially predict yet undiscovered mechanisms (Field, D. J., 1987; Zhu, S. C. and Mumford, D., 1997; Simoncelli, E. P. and Olshausen, B. A., 2001). In the remainder of this chapter we review many of the known statistical properties of natural images: first-order spatial statistics of luminance and contrast, second-order spatial amplitude spectrum, higher-order statistical properties (insofar as they are known), and temporal statistics. For each property we review and discuss the various ways in which the visual system is optimized to reduce redundancy and exploit these statistical regularities.

1.17.2 Luminance and Contrast

The first-order spatial and temporal statistics of natural images describe the mean luminance values found across a large distribution of such images. The luminance of natural images can vary over several orders of magnitude, even within a single scene (van Hateren, J. H., 1993; Frazor, R. A. and Geisler, W. S., 2006). However, absolute luminance information is not a particularly useful measure for identifying specific image content. In accordance with the principle of redundancy reduction, many animals have evolved specialized neural machinery that compresses the luminance information in natural images (Fain, G. L. *et al.*, 2001). Nonlinear luminance gain control mechanisms are found in the photoreceptors of many insects (Laughlin, S. B., 1994; van Hateren, J. H., 1997), and in the mammalian retina (Fain, G. L. *et al.*, 2001) and lateral geniculate nucleus (LGN; Mante, V. *et al.*, 2005). Regardless of the species, these mechanisms convert the wide dynamic range of natural luminance signals into a more coarsely coded signal that still preserves critical information about relative luminance.

The local contrast in any natural image can also vary over a wide range. Local contrast is correlated with important structural features of natural scenes, such as edges, that are useful for scene segmentation (Marr, D. and Hildreth, E., 1980) and for guiding eye movements and attention (Reinagel, P. and Zador, A. M., 1999; Einhauser, W. *et al.*, 2006). However, local contrast gives little information about the specific features that are present in a scene. Therefore many animals have evolved a wide variety of nonlinear contrast gain control mechanisms that operate at both peripheral (Shapley, R. and Victor, J. D., 1979) and more central (Albrecht, D. G.

et al., 1984; Lennie, P. and Movshon, J. A., 2005) stages of visual processing. These mechanisms normalize contrast variation in order to minimize the computational resources necessary to represent and process natural visual images, and enhance the effective contrast of important features in a scene.

Although contrast is partially a function of luminance, in natural images these quantities are statistically independent (Mante, V. *et al.*, 2005; Frazor, R. A. and Geisler, W. S., 2006). The independence of luminance and contrast in natural images probably reflects the presence of specific structural elements whose higher-order statistics influence local contrast (Frazor, R. A. and Geisler, W. S., 2006). In order to remove redundant information about luminance and contrast while preserving potentially important information about the relationship between the two, the luminance and contrast gain control mechanisms in the mammalian visual system work independently (Mante, V. *et al.*, 2005).

The examples given here illustrate how visual systems exploit useful information in the simple first-order statistics of natural images while removing less informative and redundant information. Much of the information about the absolute magnitude of luminance and contrast is removed, while information about the variation of these quantities across each image is retained.

1.17.3 The Amplitude Spectrum and Scale Invariance

The second-order spatial statistics of natural images describe correlations between pairs of pixels. These relationships are summarized most conveniently by the amplitude spectrum. The amplitude spectrum of natural images has a characteristic 1/f profile (where f is spatial frequency; Field, D. J., 1987); low spatial frequencies tend to have the most power and power decreases at higher frequencies. Although natural images have a 1/f amplitude spectrum on average, the spectrum of any specific image may deviate somewhat. The 1/f profile reflects the fact that nearby pixels in a natural image tend to have similar luminance, but pixels far from one another tend to be less similar. This property is believed to reflect a fundamental scale invariance property of natural scenes (Field, D. J., 1994; Ruderman, D. L., 1997; Balboa, R. M. *et al.*, 2001; Lee, A. B. *et al.*, 2001).

Like luminance and contrast, the 1/f amplitude spectrum is a general property of natural images and gives little information about the specific content of a scene. In fact, theoretical studies suggest that a maximally efficient visual system should simply whiten the amplitude spectrum to remove the 1/f bias (Barlow, H. B., 1961; Atick, J. J., 1992; van Hateren, J. H., 1993; Dong, D. W. and Atick, J. J., 1995b). Whitening mechanisms have been found in both insects (Srinivasan, M. V. *et al.*, 1982) and mammals (Dan, Y. *et al.*, 1996). Psychophysical studies have shown that humans are remarkably insensitive to the power spectrum of natural images (Piotrowski, L. N. and Campbell, F. W., 1982; Tadmor, Y. and Tolhurst, D. J., 1993; Thomson, M. G. A. and Foster, D. H., 1997), suggesting that the human visual system also uses whitening to maximize information transmission during natural vision.

1.17.4 Optimal Basis Sets for Representing Natural Images

Several studies have sought to identify the optimal set of primitives (or basis functions) that could be used to represent natural scenes. The simplest primitives would be a set of linear filters that optimally describe any natural image according to some specific statistical criterion. In some of the earliest work on natural image statistics, Field D. J. (1987; 1994) argued that a sparseness criterion would provide an optimized representation of natural scenes. A sparse representation is one that contains a large number of filters selected such that a relatively small proportion of them is required to encode any specific scene. Thus, although a sparse representation requires many neurons, it minimizes overall metabolic costs (Laughlin, S. B. *et al.*, 1998). Others have argued that the best representation for natural scenes consists of linear filters whose responses to natural images are statistically independent (called independent components; Bell, A. J. and Sejnowski, T. J., 1997). However, the sparseness and independence criteria are closely related, and both produce filters that are spatially localized functions tuned to a limited range of orientations and spatial frequencies (Bell, A. J. and Sejnowski, T. J., 1997; Olshausen, B. A. and Field, D. J., 1997; Hyvarinen, A. and Hoyer, P., 2000; Willmore, B. *et al.*, 2000). These filters are known as Gabor wavelets (Daugman, J. G., 1988), and any natural image can be constructed from some combination of these Gabor wavelets.

If one goal of visual processing is to generate a sparse representation of natural scenes then we

would expect the early visual system to embody Gabor wavelets. Indeed, the Gabor wavelet model was used to describe receptive field organization in primary visual cortex even before the connection between Gabor wavelets and natural images was understood (Daugman, J., 1980; Daugman, J. G., 1988). Several studies have now demonstrated that the Gabor wavelet model provides a good description of how simple cells in primary visual cortex encode natural scenes (Smyth, D. *et al.*, 2003; David, S. V. *et al.*, 2004; Prenger, R. *et al.*, 2004; Felsen, G. *et al.*, 2005; Touryan, J. *et al.*, 2005).

1.17.5 More Complex Spatial Properties

Natural scenes possess a wealth of higher-order statistical information beyond luminance, contrast, and the amplitude spectrum (Field, D. J., 1987): by one estimate, the distribution of natural images has almost twice the structural regularity of a distribution of noise with the same power spectrum (Chandler, D. M. and Field, D. J., 2007). These higher-order statistical properties are captured in the phase spectrum, which describes the alignment of spatial frequencies within an image. The image structure described by the phase spectrum is critical for successful interpretation of natural scenes (Piotrowski, L. N. and Campbell, F. W., 1982; Tadmor, Y. and Tolhurst, D. J., 1993; Thomson, M. G. A. and Foster, D. H., 1997).

Several lines of evidence indicate that human perception and interpretation of natural scenes depends primarily on their higher-order statistics. An image that has a $1/f$ amplitude spectrum but no higher-order structure looks like a picture of wispy clouds and does not appear to contain any solid surfaces (see Figure 1). When a new image is constructed by combining the power spectrum of one image and the phase spectrum of another, perception is dominated by the phase spectrum, not the power spectrum (see Figure 1; Piotrowski, L. N. and Campbell, F. W., 1982; Tadmor, Y. and Tolhurst, D. J., 1993; Thomson, M. G. A. and Foster, D. H., 1997). Human contour detection and grouping performance have also been shown to reflect the co-occurrence statistics of contour elements found in natural scenes (Geisler, W. S. *et al.*, 2001), and these higher-order statistics are also critically dependent on information contained within the phase spectrum.

Although higher-order structure of natural scenes is critical for accurate perception of the world, relatively little is currently known about the neural mechanisms that are responsible for processing and interpreting this information. However, there is strong evidence that such mechanisms exist even in primary visual cortex. The diversity of neuronal responses observed in V1 during stimulation with natural images is much larger than would be expected if V1 neurons could be modeled perfectly as Gabor wavelets (Weliky, M. *et al.*, 2003; Felsen, G. *et al.*, 2005; Yen, S. C. *et al.*, 2007), and the Gabor wavelet model of V1 only predicts about half of the potentially explainable variance in natural visual responses (David, S. V. and Gallant, J. L., 2005).

One neural mechanism that is likely to play an important role in encoding complex structure in natural scenes is the nonclassical surround (nCRF; Wegmann, B. and Zetzsche, C., 1990; Vinje, W. E. and Gallant, J. L., 2000; 2002; Karklin, Y. and Lewicki, M. S., 2003; 2005). The nCRF is a region surrounding the classical receptive field (CRF) of each visual cortical neuron. Although stimuli falling in the nCRF do not elicit spikes directly, they modulate responses to stimuli occurring within the CRF. The predominant function of the nCRF is divisive normalization (Heeger, D. J. *et al.*, 1996), which probably reduces the influence of weak correlations amongst filters in the Gabor wavelet representation of natural scenes (Wegmann, B. and Zetzsche, C., 1990; Krieger, G. *et al.*, 1997; Simoncelli, E. P. and Schwartz, O., 1998; Thomson, M. G. A., 1999; Zetzsche, C. and Krieger, G., 1999; Schwartz, O. and Simoncelli, E. P., 2001). However, the nCRF also contains secondary mechanisms that likely exploit specific correlations between Gabor wavelets that reflect specific structural elements in natural scenes, such as edges and corners (Wegmann, B. and Zetzsche, C., 1990; Vinje, W. E. and Gallant, J. L., 2000; Schwartz, O. and Simoncelli, E. P., 2001; Zetzsche, C. and Rohrbein, F., 2001).

What about still more complex aspects of natural scenes? The primate visual system consists of a complex hierarchical network of numerous distinct visual areas (Van Essen, D. C. and Gallant, J. L., 1994; Tootell, R. B. H. *et al.*, 2003), and it is likely that these areas exploit more complex statistical regularities. Unfortunately little is currently known about the statistical structure of natural images beyond second order (Krieger, G. *et al.*, 1997; Thomson, M. G. A., 1999), so it is difficult to test this idea directly. The few studies that have investigated neural coding

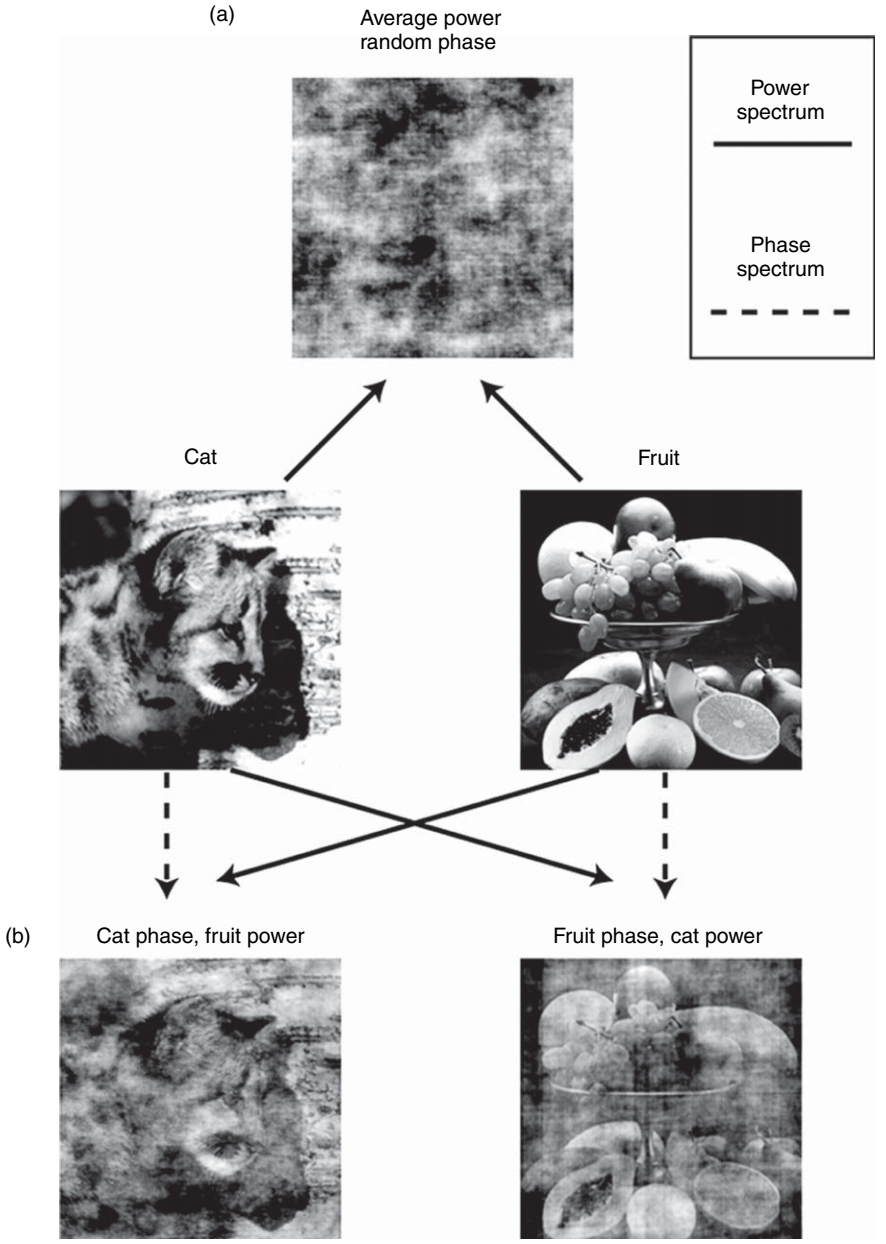

Figure 1 The phase spectrum largely determines the perception of structure in natural images, and the power spectrum has relatively little influence. (a) Two distinct images (a cat and a bowl of fruit, second row) are recombined by taking the Fourier transform of each image, discarding their phase spectra and averaging their power spectra (solid lines). The average power spectrum (not shown) is then combined with the phase spectrum of a sample of Gaussian white noise and inverse-Fourier transformed (top row). The resulting image appears as a wispy cloud and has no discernable structure. (b) The left panel shows the phase spectrum of the cat image (dotted line) combined with the power spectrum of the fruit bowl image (solid line). The right panel shows the phase spectrum of the fruit bowl image (dotted line) combined with the power spectrum of the cat image (solid line). In both cases the resulting images are dominated by the phase spectrum, not the power spectrum.

of natural images in extrastriate visual areas have focused on area V4 and the inferior-temporal complex. Studies using simple stimuli have suggested that V4 neurons are selective for complex shapes (Gallant, J. L. *et al.*, 1993; Pasupathy, A. and Connor, C. E., 1999; Gallant, J. L. *et al.*, 2000), and recent work confirms that these cells extract specific higher-order structure from natural scenes (David, S. V. *et al.*,

2006). Neurons downstream of V4 are also selective for complex features (Gross, C. G. *et al.*, 1972; Perrett, D. I. *et al.*, 1982; Desimone, R. *et al.*, 1984; Tanaka, K. *et al.*, 1991; Miyashita, M., 1993; Foldiak, P. *et al.*, 2003), but no study has yet linked complex feature tuning in these areas to the higher-order statistics of natural images. However, there is some evidence that the inferior temporal complex is optimized to encode natural scenes efficiently (Baddeley, R. *et al.*, 1997).

1.17.6 Temporal Statistics of Natural Images

Thus far we have discussed the spatial statistics of natural images, but these only describe the properties of still images taken by a stationary camera aimed at a stationary world. Real natural images are dynamic and change over time. Complete understanding of natural images also requires consideration of their temporal statistics: how their statistical properties change over time.

Many of the spatial statistics of natural images have analogous distributions in the temporal domain. For example, in certain regimes the temporal amplitude spectrum of natural images is 1/f (Dong, D. W. and Atick, J. J., 1995a; van Hateren, J. H. and van der Schaaf, A., 1996): low temporal frequencies tend to have the most power and power decreases at higher frequencies. Thus, natural images are temporally scale invariant. Because temporal scale invariance gives little information about the specific content of a scene, an efficient visual system should tend to whiten the temporal amplitude spectrum in order to reduce redundancy (Dong, D. W. and Atick, J. J., 1995b). Such temporal whitening mechanisms have been found in both insects and mammals (Dong, D. W. and Atick, J. J., 1995b; van Hateren, J. H. *et al.*, 2005).

One important property of natural images is that their spatial and temporal statistics are not separable (Dong, D. W. and Atick, J. J., 1995a). Theory suggests that this statistical regularity can be exploited by processing signals through multiple channels, some tuned to low spatial and high temporal frequencies, others tuned to high spatial and low temporal frequencies (Dong, D. W. and Atick, J. J., 1995b; van Hateren, J. H. and Ruderman, D. L., 1998). Separate, parallel pathways of this type have been found at many different stages of visual processing in mammals (Merigan, W. H. and Maunsell, J. H., 1993). One might speculate that this statistical property of natural images may have driven the development of separate ventral and dorsal streams in the mammalian visual system.

Some of the properties of neural coding in primary visual cortex that have been difficult to explain in terms of the spatial statistics of natural images might reflect the influence of temporal statistics. For example, although the sparseness criterion can explain the presence of Gabor wavelet filters in primary visual cortex, it cannot account for why many of these neurons are insensitive to spatial phase (Hubel, D. H., 1959). However, a different criterion that can exploit the statistical regularity of signals over time can account for phase invariance (Wiskott, L. and Sejnowski, T. J., 2002; Berkes, P. and Wiskott, L., 2005). This criterion, known as slow feature analysis, assumes that the visual system should be driven to represent those features in natural images that tend to change most slowly over time (because those features are most likely to represent important structural elements in natural scenes).

The temporal statistics of natural images are not determined entirely by the motion of objects in a scene; they are also influenced by saccadic eye movements and by the motion of the observer through the environment. Saccadic eye movements have a large effect on the temporal statistics of natural images, because they break long temporal correlations and introduce a substantial temporal transient after each saccade (David, S. V. *et al.*, 2004). The motion of the observer through the environment must also influence image statistics, though this has not yet been characterized.

Both the spatial and temporal statistics of natural images are stationary over long timescales. However, these statistics can change greatly from one moment to the next, due to changes in the scene itself, motion of the observer or eye movements. To maximize processing efficiency under such changing conditions the visual system should adapt to the prevailing statistical structure (Brenner, N. *et al.*, 2000). Dynamic adaptation in response to changes in stimulus statistics has now been observed at many different stages of visual processing: in the retina (Shapley, R. and Victor, J. D., 1979), LGN (Lesica, N. A. *et al.*, 2003; Lesica, N. A. and Stanley, G. B., 2004; Solomon, S. G. *et al.*, 2004), and even in the visual cortex (David, S. V. *et al.*, 2004; Sharpee, T. O. *et al.*, 2006). These pervasive adaptation effects allow the visual system to optimize both redundancy reduction and signal exploitation dynamically under changing conditions.

1.18.1 Introduction

In starlight, only a few rod photoreceptors out of every 10 000 absorb photons during the ~200 ms integration time of rod signals. Yet this weak signal, embedded in noise arising in the remaining rods, can guide visual behavior. Understanding how vision under these conditions is possible provides an excellent opportunity to bring together biophysical studies of single molecules and synapses, computational studies of signal processing and neural coding, and behavioral studies of the overall system reliability.

Vision near absolute threshold requires that rods respond to single absorbed photons, that retinal synapses reliably transmit the resulting signals, and that the response to each absorbed photon is amplified to produce a noticeable change in ganglion cell spiking. Meeting these requirements challenges our understanding of several basic issues in neuroscience: sensory transduction, synaptic transmission, and neural coding. This chapter focuses on what is known about how these challenges are met and the general insights these studies have provided about neural function.

1.18.2 Behavior

The ability of human observers to detect absorption of a small number of photons has been appreciated for more than 100 years (reviewed by Field, G. D. *et al.*, 2005). It is clear from this long history of behavioral measurements that dark-adapted visual sensitivity approaches the limits set by the division of light into discrete photons and the consequent statistical fluctuations in photon absorption. This exquisite sensitivity imposes a set of constraints on the neural mechanisms responsible for detecting and processing signals from single-photon absorptions. This section briefly reviews behavioral measurements of absolute

sensitivity and describes the constraints that these measurements impose.

1.18.2.1 Statistical Variations in Photon Absorption

The physics of light itself imposes a key constraint on the reliability of rod vision. Figure 1 illustrates the impact of statistical fluctuations in photon absorption on the fidelity of signals in the rod photoreceptor array. Each pixel in the image represents, on a gray scale, the photon absorption rate in a single rod photoreceptor. Nominally constant light from an object in the visual scene will produce a time-varying rate of absorbed photons – for example, light that produces an average of five absorbed photons in 1 s will sometimes produce four, sometimes five, sometimes six absorbed photons. Similarly, these statistical fluctuations cause nominally homogeneous objects to produce spatially varying numbers of absorbed photons. The probability of obtaining n absorbed photons, given the mean number absorbed, follows Poisson statistics. A key property of Poisson statistics is that the variance in the event count is equal to the mean – thus the standard deviation of the number of absorbed photons is $\sqrt{m}$ for a mean of m.

Although Poisson fluctuations in photon absorption are present at all light levels, they have a particularly striking impact on the fidelity of inputs to the retina at low light levels. Thus in Figure 1 the mean number of absorbed photons in a single simulated rod is 1000 for the left panel, 10 for the middle panel, and 0.1 for the right panel. The histograms below the images show the distribution of the number of absorptions across rods. The impact of Poisson fluctuations increases as light levels fall. Assuming that each image in Figure 1 represents the photons absorbed in one 200 ms rod integration time, even the right panel is a factor of 100–1000 above absolute visual threshold and hence does not accurately capture how much the light inputs to the retina can vary. Poisson fluctuations in photon absorption such as those depicted in Figure 1 are unavoidable and impose a fundamental limit to visual fidelity that no imaging device can exceed.

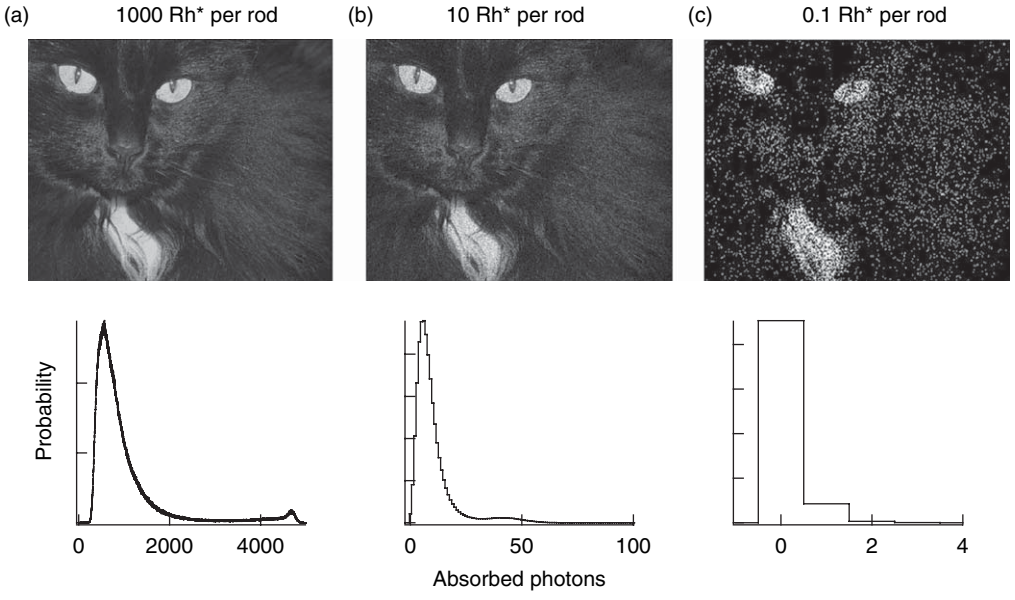

Figure 1 Simulation of Poisson fluctuations in the rod array. The top images represent the pattern of photon absorptions produced in a 2000 × 1500 array of rod photoreceptors in a single time period (e.g., a single 200 ms period corresponding to the integration time of the rod signals). Each pixel in the image corresponds to a single rod, with the gray scale encoding the number of absorbed photons (different gray scale for each image). The bottom histograms show the distributions of photon absorptions across simulated rods. The left panel is for a mean of 1000 photons per rod, the middle for 10 photons per rod, and the right for 0.1 photons per rod. The images were created in two steps. First, the pixel values of the original image were all scaled by a single constant so that the mean corresponded to the desired mean number of absorbed photons. Second, each pixel was replaced with a single sample from a Poisson distribution with a mean equal to the scaled pixel value from the first step.

1.18.2.2 Behavioral Estimates of Absolute Sensitivity and Dark Noise

How does the sensitivity of rod vision compare to limits imposed by the irreducible noise produced by Poisson fluctuations in photon absorption? Most behavioral experiments attempting to answer this question have used the frequency of seeing approach introduced by Hecht S. *et al.* (1942) and van der Velden H. A. (1946). The basic experiment is simple – on each trial a dark-adapted observer is asked to say 'yes' if he/she saw a flash, and the probability of seeing is plotted against the number of photons delivered to the cornea. Observers are cued at the beginning of the trial and are trained to a certain rate of false positive responses – that is, 'yes' responses when no flash was delivered. Such false-positive responses originate from noise within the visual system (see below). Figure 2(a) shows the measured frequency of seeing curve for one observer from the classic experiments of Hecht, Shlaer, and Pirenne.

Interpretation of experiments like that in Figure 2(a) would be simpler if we could convert the *x*-axis from the number of photons at the cornea to the number of photons absorbed within the rod photoreceptor array. However, the probability that a photon incident on the cornea is absorbed within the rod array is not well characterized even today. Hecht, Shlaer, and Pirenne instead estimated behavioral threshold from the variability in an observer's responses to a nominally fixed strength flash – for example, for the observer in Figure 2(a) a flash producing 90 photons at the cornea was seen ~50% of the time. Hecht, Shlaer, and Pirenne explained the broad range of flash strengths over which an observer generated variable responses based on two assumptions: the dominant source of noise was Poisson fluctuations in photon absorption and observers answered 'yes' only when more than a threshold number of photons were absorbed. Thus on some trials at a given flash strength, fewer than the threshold number of photons will be absorbed and the flash will go unseen, while on other trials the number absorbed will exceed the threshold and the flash will be seen. For a given threshold, the cumulative Poisson distribution predicts how the detection probability depends on the number of absorbed photons (Figure 2(b)). In particular, the width of the transition between seen and unseen flashes depends on threshold.

An advantage of the analysis described above is that the unknown probability that a photon at the cornea is absorbed in the rod array is naturally separated from the threshold by plotting the detection probability against the logarithm of the number of photons at the cornea as in Figure 2; in this case, the unknown absorption efficiency shifts the Poisson predictions along the *x*-axis while the shape is uniquely determined by the threshold (see Figure 3, right).

From the analysis described above, Hecht, Shlaer, and Pirenne concluded that the threshold for

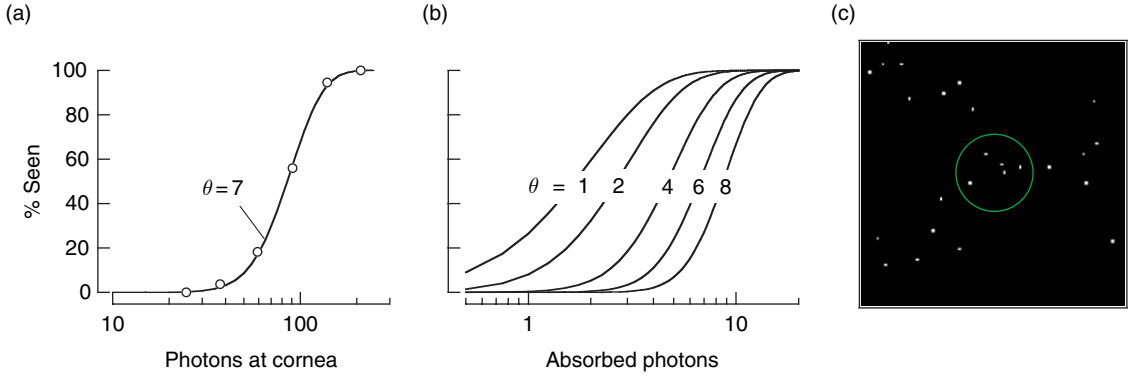

Figure 2 Frequency of seeing analysis. (a) Probability of yes response plotted against the mean number of photons delivered to the cornea for one observer from Hecht S. *et al.* (1942). (b) Theoretical frequency of seeing curves for different thresholds θ. Each point on each curve corresponds to a cumulative Poisson distribution for getting θ or more absorbed photons given the mean number of absorptions at each *x*-axis location. (c) Dark light and false positives. Simulated pattern of photon absorptions and photon-like noise events in the rod array. The green circle denotes the rods receiving incident photons. Internal noise in the visual system can be expressed as a rate of photon-like noise events in the rods (a dark light), shown here as a small subset of rods (e.g., those outside the green circle) generating photon-like responses though they did not absorb a photon. This dark light can be compared directly with real incident light, simplifying the estimates of the relationship between false positives and dark noise.

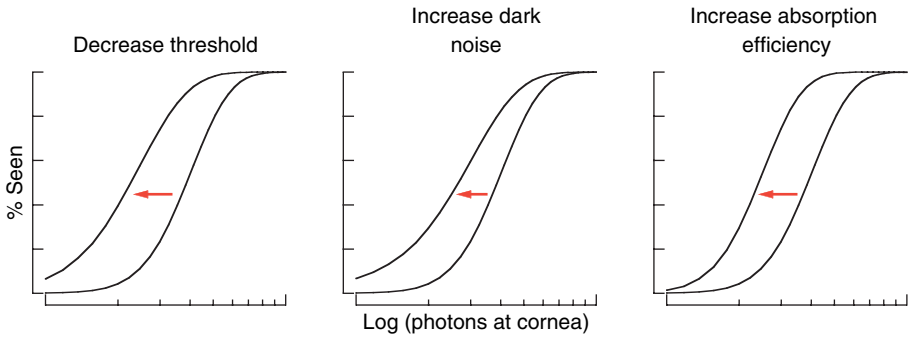

Figure 3 Ambiguities in fitting frequency of seeing curves. Predicted changes in frequency of seeing curves produced by changes in threshold (left), dark noise (middle), and absorption efficiency (right).

seeing was five to seven absorbed photons. Under the conditions tested, they also concluded that Poisson fluctuations were the dominant noise source producing variability in an observer's responses. Contemporary experiments by van der Velden H. A. (1946) concluded that the threshold was closer to two absorbed photons, leading to a speculation that the visual system detected coincident photon arrivals. The difference between these two estimates of threshold likely reflects differences in the rate of accepted false-positive responses from the observers (Marriot, F. H. *et al.*, 1959).

Subsequent experiments by Barlow H. B. (1956), Sakitt B. (1972), and Teich M. C. *et al.* (1982) allowed observers to adopt a less stringent criterion for detecting a flash, resulting in a higher (i.e., easily measurable) rate of false-positive responses. A non-zero false-positive rate indicated noise in addition to Poisson fluctuations in photon absorption, since no Poisson fluctuations are present on trials when no light is delivered. Hence the false-positive rate provides an estimate of noise within the visual system. It is convenient to express this noise as an equivalent background or dark light, which can be compared directly with true visual inputs (Figure 2(c)). Thus when the noise causes more than a threshold number of photon-like events, it also causes the perception of a flash – that is, a false-positive response. Assuming that the dark light and fluctuations in photon absorption are independent and additive, the dark light is easily incorporated into the fits to the frequency of seeing curves by adding a constant rate of photon-like events to those produced by the flash. The dark light estimated in these studies was approximately 0.01 equivalent photon-like events per rod per second. A second important finding in these studies was that observers could trade an increase in the rate of false-positive responses for a decreased threshold. This is consistent with the underlying neural signals that vary in a graded manner with the number of absorbed photons rather than signals that require a threshold number of photon absorptions to be produced.

1.18.2.3 Limitations to Behavioral Experiments

A key limitation to interpreting behavioral experiments on absolute visual sensitivity is that the fits to the frequency of seeing curves are not unique. In particular, changes in detection threshold, dark noise, and absorption threshold all produce similar (though not identical) changes in the shape of the frequency of seeing curves (Figure 3), and thus these parameters can trade against each other in fitting the data. For example, an increased threshold shifts the frequency of seeing curve to the right along the flash strength axis and makes it steeper (Figure 3, left), while an increase in dark noise has the opposite effect (Figure 3, middle). Absorption efficiency can similarly trade against other parameters (Figure 3, right). Plausible estimates of the absorption efficiency range from 0.05 to 0.3, producing a $\sim$ tenfold range in behavioral estimates of internal noise and detection threshold (Donner, K., 1992; Field, G. D. *et al.*, 2005).

The quantitative uncertainty in behavioral estimates of absolute sensitivity has a qualitative effect on how we view retinal processing. The low end of the behavioral estimates, as is often emphasized, is in good agreement with limits to sensitivity imposed by the rods (see below), implying that the remainder of the visual system operates effectively noiselessly and efficiently. If true, this is a strong constraint.

1.18.2.4 Constraints Imposed by Behavior

Despite the uncertainties in interpreting behavioral measures of absolute sensitivity, it is clear that a relatively small number of photons is required for detection and that Poisson fluctuations in photon absorption pose an important noise source limiting behavioral sensitivity. These observations serve to motivate a set of questions about phototransduction in the rod photoreceptors and the retinal processing of the resulting signals: How is the signal from a single activated rhodopsin molecule amplified in the rods and in the retinal circuitry? How does the retina maintain low noise so as not to swamp the single-photon responses? Are there mechanisms in the retinal circuitry that separate the signal of interest from noise that threatens to obscure them?

1.18.3 Responses of Rod Photoreceptors to Single Photons

Behavioral sensitivity unambiguously requires that rod photoreceptors detect a single absorbed photon since flashes producing much less than one photon absorbed per rod are detected. The rods perform this task admirably, with a performance that compares favorably with the best man-made room temperature light detectors. Understanding how this performance is achieved with components restricted to proteins and lipids has been a major achievement (see Chapter Phototransduction in Rods and Cones). As described below, the rods meet several functional requirements for reliable photon detection: (1) they efficiently capture incident photons; (2) they amplify the signals resulting from the activation of a single rhodopsin molecule by an absorbed photon to produce a macroscopic electrical response; (3) they maintain low dark noise; and (4) they generate near-identical responses to each absorbed photon.

1.18.3.1 Photon Capture

The first step in detecting single photons is capturing them. Rhodopsin is packed onto the surface of membrane disks in the rod outer segment at sufficiently high density to hinder protein diffusion on the disk (Pugh, E. N. and Lamb, T. D., 1993). This high density ensures that the majority (~70%) of photons that enter one end of the cylindrical outer segment are absorbed. Rhodopsin is a member of the G protein-coupled receptor family, and hence active rhodopsin catalyzes G protein activation. Rhodopsin is composed of two parts: a light-sensitive chromophore and the opsin protein that houses it (see Chapter Mammalian Photopigments). Absorption of a photon by the 11-*cis*-retinal chromophore produces an electronic excitation, which with high efficiency produces a *cis–trans* conformational change of the chromophore. The change in chromophore conformation in turn produces a change in the conformation of the opsin, rendering rhodopsin catalytically active. The steps between photon absorption and opsin activation occur with high efficiency – 60–70% of the absorbed photons lead to opsin activation (Dartnall, H. J. A., 1972; Baylor, D. A. *et al.*, 1979). The high rhodopsin content and high quantum efficiency of opsin activation together mean that 40–50% of the photons incident on the rod outer segment are converted into active rhodopsin molecules.

1.18.3.2 Amplification

As predicted by behavioral studies, rods generate discernable electrical responses to single absorbed photons (Baylor, D. A. *et al.*, 1979). In darkness, rods maintain a constant circulating current that flows into the outer segment and out of the inner segment. Light activates the phototransduction cascade and suppresses the current. Figure 4(a) shows the change in outer-segment membrane current of a primate rod in response to a repeated fixed-strength flash producing, on average, 0.5 effective photon absorptions (Rh^*). The rod responds to some flashes and fails to respond to others. The discreteness of the responses indicates an elementary response of ~2 pA in amplitude.

Two arguments indicate that the elementary response is produced by the absorption of a single photon rather than, for example, the coincident activation of two rhodopsin molecules or by an all-or-none response such as an action potential (Baylor, D. A. *et al.*, 1979). First, the trial-to-trial variations in the response are in good agreement with expectations from the Poisson statistics that govern photon absorption. Figure 4(b) (middle and right) plots histograms of the amplitudes of the responses to two different flash strengths measured in the same cell. The smooth curves show fits assuming that the number of photons absorbed obeyed Poisson statistics (Figure 4(b), left) and that the dark noise and noise in the elementary response were independent and additive. The key point is that the fits have been constrained so that the mean of the Poisson distribution used for the right panel is four times that used in

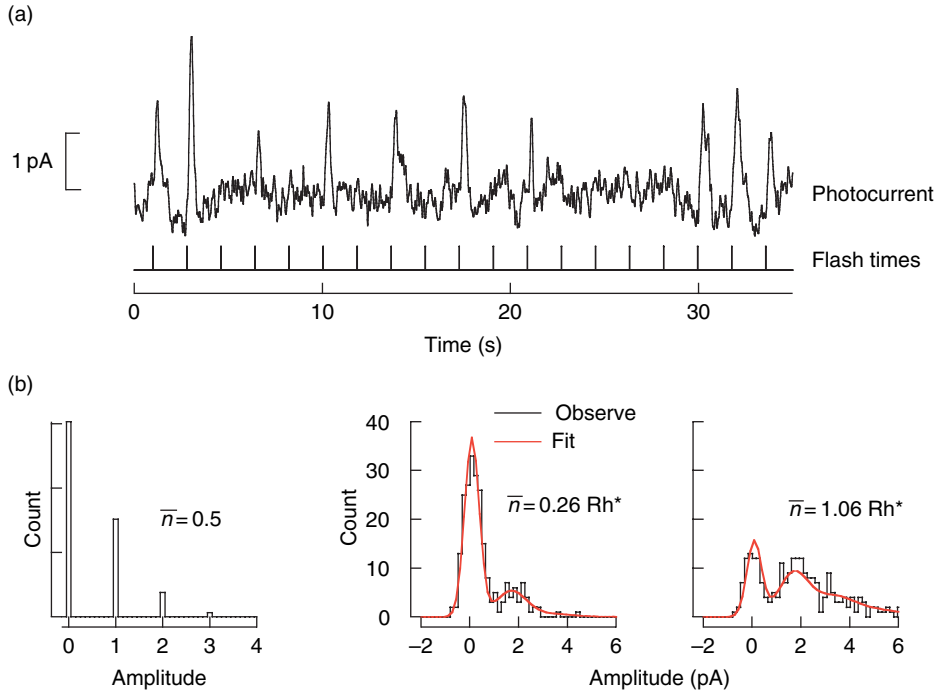

Figure 4 Rods respond to single photons. (a) Changes in the outer segment membrane current of a primate rod in response to a repeated fixed-strength flash. Currents were measured with a suction electrode. Flash timing is shown below the current record. This flash produced, on average, 0.5 Rh*. (b) Fits to amplitude histograms. Left panel shows the probability of 0, 1, and 2 absorbed photons calculated from a Poisson distribution with a mean of 0.5 absorbed photons per trial. The middle and right panels plot measured amplitude distributions for two different flash strengths that differ by a factor of 4. Peaks near 0 correspond to trials in which the cell failed to respond and the peak near 2 pA corresponds to the elementary responses. The smooth curves fit to the measured distributions are calculated assuming that the number of events per trial follows a Poisson distribution and that the noise in darkness and in the elementary response are independent and additive. The fits were constrained such that the means of the underlying Poisson distributions differed by a factor of 4, corresponding to the difference in flash strengths. Data from Greg Field.

the middle panel, corresponding to the fourfold difference in flash strengths used to collect two sets of responses. The scaling of the number of responses in the peaks centered at 0, 2, and 4 pA (corresponding to 0, 1, and 2 elementary responses) with flash strength is consistent with expectations from Poisson statistics and inconsistent with models in which the elementary response depends on more than one absorbed photon.

The second argument linking the rod's elementary response with activation of a single rhodopsin molecule comes from the agreement of different measures of a cell's ability to absorb incident photons. First, direct optical measures of the fraction of incident photons absorbed by the rod have been compared with measures of the number of elementary electrical events elicited by calibrated flashes (Baylor, D. A. *et al.*, 1979). These experiments indicate that 60–70% of the absorbed photons produce electrical responses, in good agreement with expectations from the quantum efficiency of rhodopsin activation. Second, the fraction of absorbed photons measured from the correspondence between calibrated photon flux (in photons per square micrometer) and elementary response probability agrees well with estimates from the rhodopsin density and the molecular absorption coefficient. Taken together, these arguments leave little doubt that the rod's elementary response corresponds to activation of a single molecule by absorption of a single photon.

Activation of a single rhodopsin molecule produces a macroscopic electrical response in the rod – on average a 1–2 pA reduction in current lasting for 200–300 ms in a primate rod (Baylor, D. A. *et al.*, 1984). This change in current produces a 1–2 mV hyperpolarization (Schneeweis, D. M. and Schnapf, J. L., 1995) and a decrease in transmitter release from the synaptic terminal. The amplification required to generate the single-photon response is nicely explained by the sequence of amplifying enzymatic reactions

that make up the transduction cascade (see Chapter Phototransduction in Rods and Cones). These events have been studied in detail using a combination of biochemical, molecular, and biophysical approaches. As a result, many of the events on phototransduction can be understood in quantitative detail (Pugh, E. N. and Lamb, T. D., 1993; Rieke, F. and Baylor, D. A., 1998a; Hamer, R. D. *et al.*, 2005). This work has made the rods the best understood of the many G protein cascades in biological systems. It also has had direct medical benefits, as we now understand the mechanisms and have potential treatments for several forms of stationary night blindness (Dryja, T. P., 2000).

The high amplification provided by the phototransduction process protects the single-photon response from noise introduced in downstream processing. The amplification in phototransduction, however, comes at the cost of a long-lasting single-photon response. This is an inevitable consequence of how second messenger cascades work: the underlying reactions require time to produce an amplified response even if they operate at or near the limit set by the rate of diffusional encounters between components (Pugh, E. N. and Lamb, T. D., 1993). The slow rod responses appear to have a considerable impact on behavior. For example, the temporal frequency at which flickering lights appear constant (flicker fusion frequency) for dark-adapted rod vision is 3–5 Hz, compared to 50–70 Hz for light-adapted cone vision (Hecht, S. and Verrijp, C. D., 1933). This difference is, at least in part, due to differences in the kinetics of the rod and cone light responses.

1.18.3.3 Dark Noise

Effective detection of single absorbed photons requires that the rods maintain low noise in darkness. The characteristics of the noise generated in the transduction process are important both functionally and mechanistically. Functionally, the properties of the noise generate testable predictions about the operation of downstream processing that aims to separate signal and noise; furthermore, noise generated in the rods is a potential source for the internal noise limiting behavioral sensitivity. Mechanistically, studies of rod noise have led to insights into the operation of the phototransduction cascade.

Figure 5 shows two sections of current recorded from a primate rod in complete darkness. Two sources of noise are apparent: occasional discrete events that have an amplitude and shape similar to the single-photon response and continuous variations in current. The discrete events originate from spontaneous activation of rhodopsin (Baylor, D. A. *et al.*, 1980). They occur once in every few hundred seconds in a primate rod at 37 °C (Baylor, D. A. *et al.*, 1984; Field, G. D. *et al.*, 2002 Neurosciences Abstract). This means that each of the 10^8 rhodopsin molecules in a primate rod activates spontaneously on average once or twice a millennium. The low rate of spontaneous activation is possible because visible photons carry considerable energy, and hence rhodopsin can be activated efficiently by 500 nm light while maintaining a large energy barrier for spontaneous activation. The temperature dependence of the rate of spontaneous activation indicates an energy barrier equal to about half the energy of a 500 nm photon (Baylor, D. A. *et al.*, 1980).

In principle, it would seem beneficial to pack more rhodopsin into the rod and capture more of the incident photons. Increasing the rod's rhodopsin content, however, would increase the rate of discrete noise events. Moreover, increasing the photon capture would require a large increase in rhodopsin content because of screening effects of other rhodopsin molecules – that is, ~70% of the incident photons are already captured and doubling the rhodopsin content would only increase this to ~90% at the cost of doubling the rate of discrete noise events. The rod's rhodopsin content comes close to optimizing the tradeoff between photon capture and discrete noise.

The continuous noise in the rod currents originates from spontaneous activation of an intermediate component (phosphodiesterase) within the phototransduction cascade (Rieke, F. and Baylor, D. A., 1996). Hence the kinetic properties of the continuous noise are determined by some of the same events that determine the kinetics of the single-photon response, and the continuous noise and single-photon response have similar (though not identical) temporal frequency content (Baylor, D. A. *et al.*, 1980; 1984). Although the continuous noise seems like an unnecessary evil, it in fact serves to keep the phototransduction cascade active in the dark, an important factor controlling the duration of the rod response (Hodgkin, A. L. and Nunn, B. J., 1988; Rieke, F. and Baylor, D. A., 1996; Nikonov, S. *et al.*, 2000). In particular, a decrease in spontaneous phosphodiesterase activation and continuous noise would slow the recovery of the single-photon response by increasing the time required for the transduction cascade to resynthesize second messengers depleted during the response (Rieke, F. and Baylor, D. A., 1996).

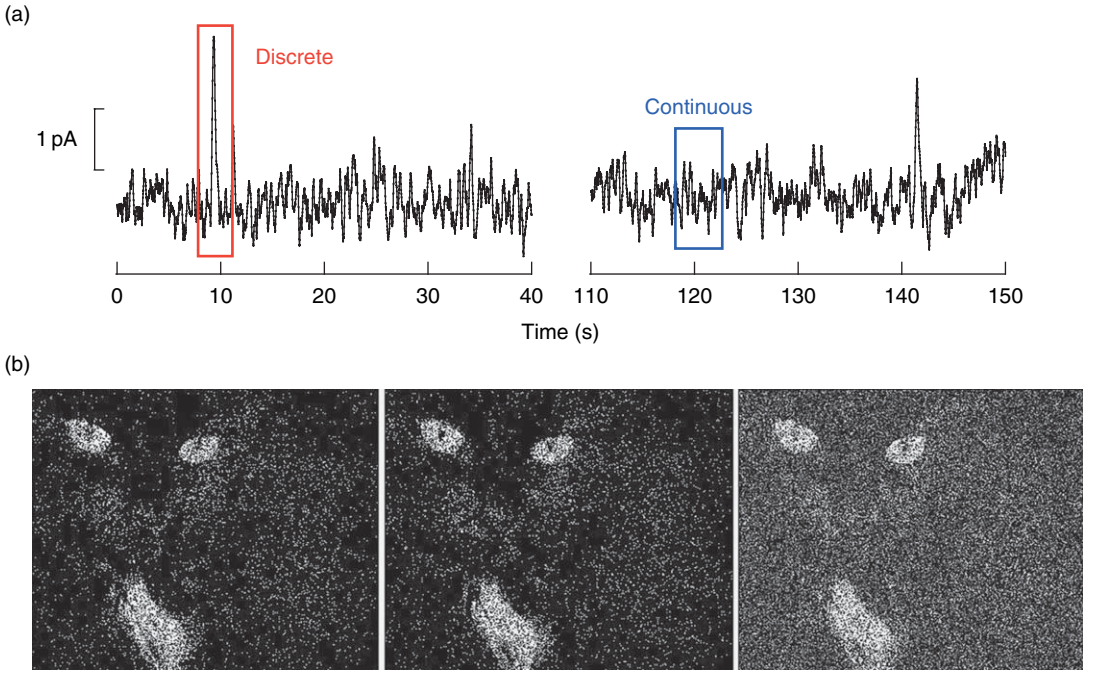

Figure 5 Dark noise and implications. (a) Two sections of dark record from a primate rod photoreceptor. Two sources of noise are apparent: continuous variations in baseline current and occasional discrete events. (b) Implications of dark noise for fidelity of signals in the rod array. The three images show the effects of Poisson fluctuations (left panel), Poisson fluctuations and discrete noise events (middle panel), and Poisson fluctuations and both discrete and continuous rod noise (right panel) on signals in the rod array. Simulations as in Figure 1. The mean number of absorbed photons per rod is 0.1 and the added noise is based on the measured noise in primate rods (discrete event probability of 0.001, continuous noise SD equal to 0.25 times single-photon response amplitude). Data from Greg Field.

Figure 5(b) illustrates the effect of dark noise on the fidelity of signals generated in the rod array. The left panel shows a simulation of the pattern of photon absorptions in the rod array for a mean of 0.1 Rh^* per rod (simulated as in Figure 1(c)). The middle panel includes discrete noise events at a probability of 0.001 per rod (corresponding to a discrete event rate of 0.005 per second and an integration time of 200 ms). Not surprisingly given the low probability of discrete events compared to incident photons, the discrete noise has little impact on the image. Except for light levels near absolute visual threshold (0.001–0.0001 Rh^* per rod per integration time), the impact of discrete noise events on the fidelity of signals in the rod array is small compared to Poisson variability in photon absorption. The right panel of Figure 5(b) shows a simulated pattern of signals in the rod array with both discrete and continuous noise added; at this intensity, continuous noise has a much more apparent effect on fidelity than discrete noise because it is present in every rod.

1.18.3.4 Reproducibility

Most signals controlled by single molecules vary considerably from one trial to the next. A familiar example is the charge flowing through an ion channel during its open time. Because the open–close transition for most ion channels is a memoryless, first-order process, the distribution of charge across multiple channel openings is exponential, with a coefficient of variation (CV; SD divided by mean) of 1. Rod responses to activation of single rhodopsin molecules show much smaller variability, with CVs of 0.25–0.35 for both the response amplitude and the area (Baylor, D. A. *et al.*, 1979; Rieke, F. and Baylor, D. A., 1998b; Whitlock, G. G. and Lamb, T. D., 1999; Field, G. D. and Rieke, F., 2002a; Doan, T. *et al.*, 2006). This reproducibility is interesting both functionally and mechanistically.

Reproducibility could permit the visual system to count absorbed photons by ensuring that responses to 0, 1, 2, etc., absorbed photons are separable. Indeed,

behavioral work suggests that dark-adapted humans can count photons (Sakitt, B., 1972), although other interpretations of the same data are possible because of the caveats raised above about behavioral estimates of absolute sensitivity (Donner, K., 1992; Field, G. D. *et al.*, 2005). Photon counting, however, is of questionable importance for visual function because of Poisson fluctuations in photon absorption – that is, a visual input producing an average of m absorbed photons will produce $m \pm \sqrt{m}$ on a single trial. The rod itself, because of reproducibility, would be capable of encoding finer gradations in light intensity.

Figure 6 compares the relative impact of Poisson fluctuations and variability in the single-photon response on signals encoded in the rod array. Figure 6(a) simulates the pattern of photon absorptions in the rod array at high light levels. Figure 6(b) is a discretized version of the image – that is, the simulated number of photons absorbed in each rod is an integer number, but Poisson fluctuations are absent. This pattern of photon absorptions is unphysical due to the lack of Poisson fluctuations, but it is useful in evaluating the relative impact of Poisson fluctuations and variability in the single-photon response since the two noise sources can be added independently. Figure 6(c) adds Poisson fluctuations in photon absorption to the image in Figure 6(b). Figure 6(d) adds variability in the single-photon response instead of Poisson fluctuations. Comparison of Figure 6(c) and (d) shows that Poisson fluctuations pose a much more severe limitation on the fidelity of the signal in the rod array than variability in the single-photon response. Only if the standard deviation of single-photon response was three to four times larger would response variability pose a limitation comparable to Poisson fluctuations. This argument applies across a wide range of mean light levels. Thus the rod appears overengineered for the task of counting incident photons.

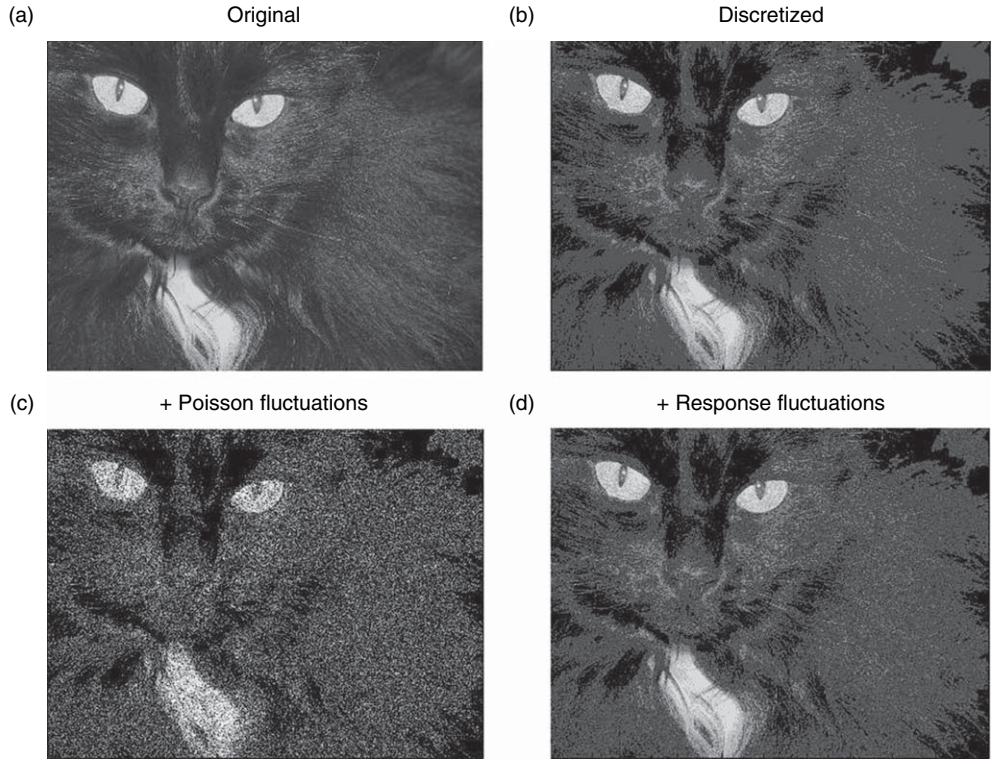

Figure 6 Reproducibility and photon counting. (a) Original image. (b) Discretized image in which the number of photons absorbed in each rod (i.e., pixel value) is an integer, with a mean of 2. (c) Image in (b) with Poisson fluctuations in photon absorption added. Each pixel in (b) was replaced by a sample from a Poisson distribution with appropriate mean. (d) Image in (b) with variability in rod's single-photon response added, assuming that the SD of the single-photon response was 0.25 times the mean. Thus each photon absorption from (b) was replaced by a sample from a Gaussian distribution with an SD of 0.25 and a mean of 1.

If photon counting is not an important consideration for rod vision, why are the rod responses reproducible? An alternative is that reproducibility is important for encoding the time of photon absorption rather than the photon count (Rieke, F. and Baylor, D. A., 1998a; 1998b; Field, G. D. and Rieke, F., 2002a). Figure 7 illustrates one test of this hypothesis. Figure 7(a) shows three individual single-photon responses recorded from a primate rod. The smooth curve in each case is a template formed from the average single-photon response; the template has been shifted along the *x*-axis to fit each single-photon response and the resulting time shift is used to estimate the apparent photon absorption time. The variability of the time shifts applied to the templates provides an estimate of the accuracy with which the photon arrival time is encoded by the single-photon response. Figure 7(b) shows a histogram of the resulting time shifts. The single-photon responses of primate rods permit estimation of the photon absorption time with a precision of ~50 ms, about 10% of the duration of the rod response (Field, G. D. *et al.*, 2002 Neurosciences Abstract). Both continuous noise and variability in the single-photon response contribute to the width of the histogram since both are present in the isolated single-photon responses. The impact of continuous noise alone can be determined by repeating this procedure using sections of dark record with added, identical single-photon responses; in this case all the variability in the responses is attributable to continuous noise. This results in the narrow histogram shown in Figure 7(b). Thus variability in the single-photon response, although small, still limits the temporal precision of the rod's single-photon response, and were reproducibility to fail temporal precision would suffer.

Reproducibility also raises an interesting molecular design question: how are the responses produced by single rhodopsin molecules controlled so that their variability is so much less than expected? Three mechanisms have been proposed: (1) saturation or compression that renders the measured current response insensitive to variations in rhodopsin's lifetime (Ramanathan, S. *et al.*, 2005); (2) feedback that reduces variability in rhodopsin's active lifetime (Whitlock, G. G. and Lamb, T. D., 1999); and (3) shutoff of a single rhodopsin molecule through a series of steps or transitions (Rieke, F. and Baylor, D. A., 1998b; Field, G. D. and Rieke, F., 2002a; Hamer, R. D. *et al.*, 2003). Each mechanism is capable of reducing variability in the single-photon response to measured levels. Direct evidence in favor of the

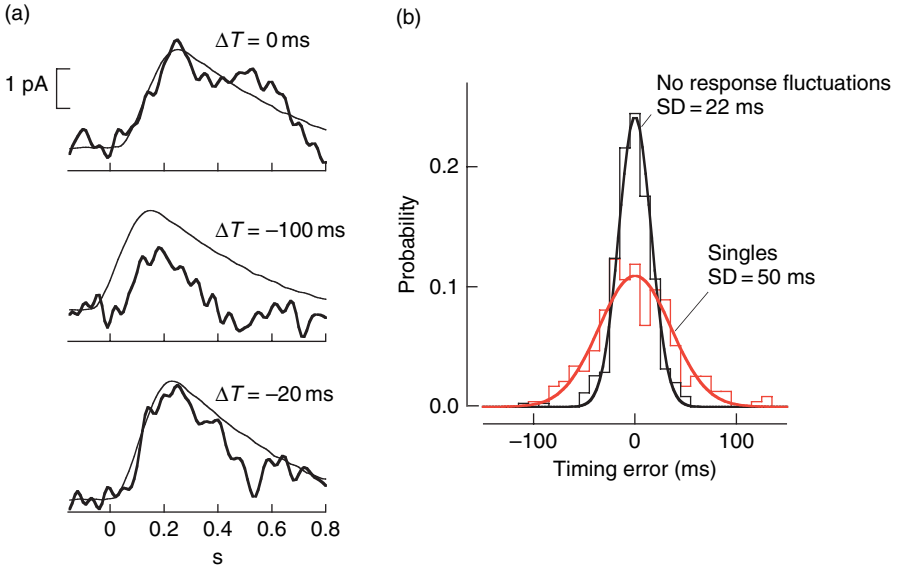

Figure 7 Reproducibility and temporal precision. (a) Three individual single-photon responses from a primate rod, each fit with a template to estimate temporal precision. Single-photon responses were identified from the responses to a repeated fixed-strength flash as in Figure 4. The template is the cell's average single-photon response. (b) Histograms of time shifts that provided best fits of the template to the single-photon responses as in (a). The red trace plots the histogram for identified single-photon responses. The black trace plots histogram for noise trials with added, deterministic single-photon response; this isolates the contribution of continuous noise to limiting temporal precision. Data from Greg Field.

multistep shutoff model comes from studying how response variability changed when rhodopsin was altered genetically (Doan, T. *et al.*, 2006). Variability of the single-photon response depends in a graded and systematic manner on the number of phosphorylation sites on rhodopsin – thus reproducibility is apparently produced by the shutoff of a single rhodopsin molecule through a series of steps, each provided by phosphorylation. This is a substantial departure from conventional models for the shutoff of single molecules. Rhodopsin is one of many G protein-coupled receptors; thus a similar strategy may decrease variability in signals controlled by other G protein cascades.

1.18.4 Retinal Readout of the Rod Signals

The elegance of photon detection by the rods would be wasted if not matched with an equally elegant readout circuit. To enable vision at low light levels, the retinal readout of signals in the rod array must meet three substantial challenges: (1) the circuitry must extract signals of relevance from the sparse pattern of photon absorptions created in the rod array; (2) the circuitry must extract and represent information about the timing of photon absorptions from the sluggish rod input signals; and (3) the circuitry must transmit and process rod signals while adding little noise.

Rod signals are conveyed across the mammalian retina through three pathways (Figure 8; see Chapter Mammalian Rod Pathways). The rod bipolar pathway is the dominant readout at low light levels (Deans, M. R. *et al.*, 2002; Volgyi, B. *et al.*, 2004) and is the focus of this section. In this pathway, rod signals are first transmitted to rod bipolar cells – a class of ON or depolarizing bipolar cell that receives only rod input. The synapse between rods and rod bipolar cells is an unusual sign-inverting glutamatergic synapse. Glutamate released from the rods in the dark activates metabotropic glutamate receptors on the rod bipolar dendrite, initiating a second messenger cascade that leads to closure of cationic channels. The decrease in glutamate release produced during the rod's hyperpolarizing light response decreases receptor activity, leading to channel opening and the production of an inward (depolarizing) current in the rod bipolar dendrites. The postsynaptic response in the rod bipolar is exceedingly rapid for one mediated by metabotropic receptors, and understanding how this cascade works is certain to be interesting. Signals in the rod bipolar are transmitted to AII amacrine cells through a more typical sign-conserving glutamatergic synapse that uses ionotropic receptors. AII amacrine cells contact ON cone bipolar cells through gap junctions and OFF cone bipolar cells through glycinergic synapses. Signals from the cone bipolar cells are then conveyed to ganglion cells. A key feature of the rod bipolar pathway is that rod and cone signals are mixed late

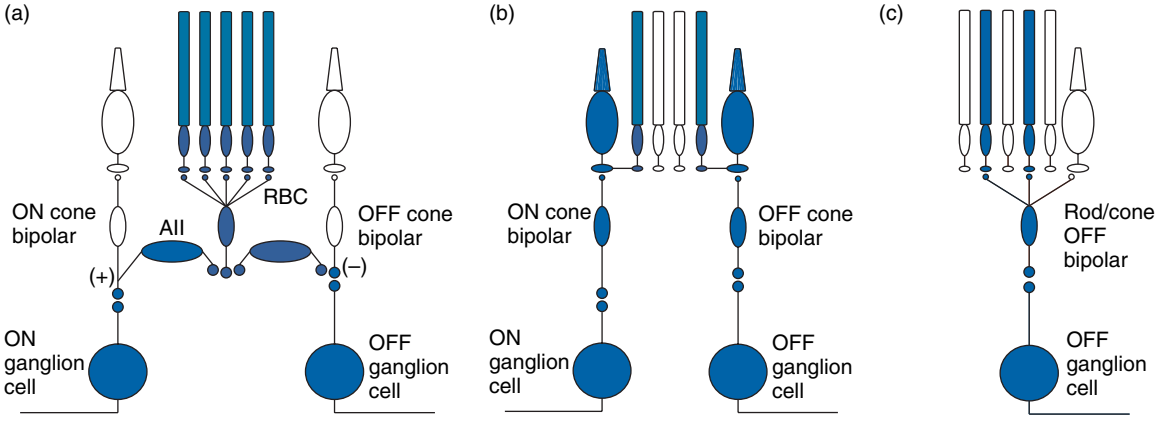

Figure 8 Pathways for rod signals in mammalian retina. (a) Rod bipolar pathway (Dacheux, R. F. and Raviola, E., 1986; Sterling, P. *et al.*, 1988). Rod signals are conveyed to ganglion cells through two dedicated cell types: rod bipolar cells and AII amacrine cells. Signals from the AII amacrine cells reach ganglion cells via ON and OFF cone bipolar cells. (b) Rod–cone pathway (Nelson, R., 1977; Schneeweis, D. M. and Schnapf, J. L., 1995). Rod signals reach cones through gap junctions and are conveyed across the cone circuitry to ganglion cells. (c) Rod–OFF cone bipolar pathway (Soucy, E. *et al.*, 1998; Hack, I. *et al.*, 1999; Tsukamoto, Y. *et al.*, 2001). Rod signals are transmitted to a class of OFF bipolar cell that receives mixed rod and cone input. AII, AII amacrine; RBC, Rod biopolar.

in retinal processing, unlike the other known pathways for rod signals in which this mixing occurs essentially immediately. Thus the rod bipolar pathway is unique in presenting multiple opportunities for rod-specific signal processing.

1.18.4.1 Sparseness, Convergence, and Nonlinear Processing

Rod vision at low light levels exemplifies a general problem: pooling of signals from an array of detectors under conditions where a small fraction of the detectors carry the signal of interest while all of the detectors generate noise. Cells throughout the nervous system face a similar issue when a small number of their converging inputs are active. This general issue is particularly tractable in the retina because the rod signal and the noise are well characterized and the relevant circuitry is well established.

Convergence is a dominant feature of rod signaling in the retina, with peripheral mammalian ganglion cells receiving input from thousands of rods. This convergence occurs in stages as signals traverse the rod bipolar pathway (Sterling, P. *et al.*, 1988): rod bipolar cells typically receive input from ~20 rods, AII amacrine cells receive input from ~500 rods via ~20 rod bipolar cells, and ganglion cells receive input from several AII amacrine cells via cone bipolar cells (Figure 9(a)). AII amacrine cells are coupled reciprocally through gap junctions, correlating signals among nearby cells (Famiglietti, E. V. J. and Kolb, H., 1975; Bloomfield, S. A. *et al.*, 1997). Signals also diverge in the circuitry: each rod contacts several rod bipolar cells, and each rod bipolar cell contacts several AII amacrine cells (Sterling, P. *et al.*, 1988; Migdale, K. *et al.*, 2003).

Corresponding to the convergence of rod signals, responses of cells late in the rod bipolar pathway saturate at lower light levels than cells early in the pathway (Pang, J. J. *et al.*, 2004; Dunn, F. A. *et al.*, 2006). Figure 9(b), top, shows families of flash responses from a mouse rod photoreceptor, a rod bipolar cell, an AII amacrine cell, and an ON ganglion cell. Each panel superimposes average responses to a series of flash strengths. The dependence of the response amplitude on flash strength for each cell type is summarized in Figure 8(b), bottom. The stimulus–response relations shift to the left for later stages in the pathway, with half-maximal flash strengths decreasing from ~10 Rh^* in the rods to ~1 Rh^* per rod in the rod bipolar cells and ~0.1 Rh^* per rod in AII amacrine and ganglion cells. Thus a flash of a given strength – for example, 0.1 Rh^* per rod – produces a larger fractional response in AII amacrine cells and ganglion cells than in the rods or rod bipolar cells.

The leftward shift of the stimulus–response relations in Figure 8(b) requires that the gain of signal transfer between cells in the rod bipolar pathway is well matched to the pattern of convergence, effectively boosting sparse single-photon responses in the rod array to create a measurable response in downstream cells. The high gain of signal transfer, together with the high gain of the phototransduction process itself, means that activation of a single rhodopsin molecule can produce a measurable change in the firing rate of a retinal ganglion cell. For example, a subset of cat ganglion cells appears to produce one to three extra action potentials when one of the thousands of rods within its receptive field absorbs a photon (Barlow, H. B. *et al.*, 1971; Mastronarde, D. N., 1983). While this high gain is essential for vision at absolute threshold, it threatens to saturate retinal responses at light levels in which only 1–2% of the rods absorb photons during the ~200 ms integration time of rod signals. Such saturation is prevented by adaptive mechanisms that decrease synaptic gain in the rod bipolar pathway (Dowling, J. E., 1963; Frishman, L. J. and Sieving, P. A., 1995; Dunn, F. A. *et al.*, 2006.

The discussion above neglects the noise that obscures the light responses of cells in the rod bipolar pathway. However, how noise is excluded, retained, or generated is central to understanding the relation between neural responses and behavior. Furthermore, noise is a key factor determining efficient strategies for retinal processing of the rod signals. Thus convergence of rod inputs creates an opportunity for downstream cells to achieve higher sensitivity than individual rods. Because of noise in the rod array, however, this opportunity would be squandered if the rod signals were simply averaged (Baylor, D. A. *et al.*, 1984; van Rossum, M. C. and Smith, R. G., 1998).

The sparse pattern of photon absorptions near visual threshold means that information about the visual inputs is carried in the responses of a small fraction (0.1–0.01%) of the rods. All of the rods, however, generate noise that threatens to obscure the responses of the few rods absorbing photons. The task facing the retina is like standing in the middle of a crowded stadium and trying to determine what a few of the thousands of people in the bleachers are yelling. Averaging responses under these

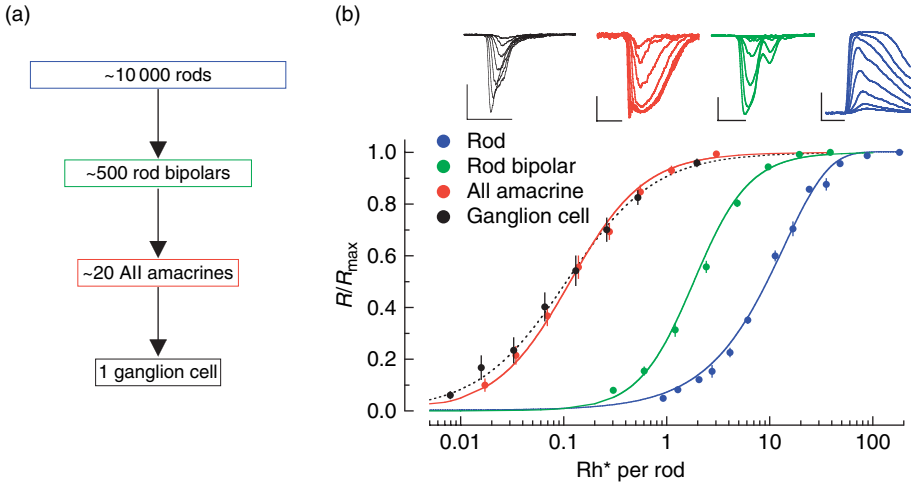

Figure 9 Convergence and stimulus–response relations for elements of rod bipolar pathway. (a) Schematic of convergence. (b) Top: Flash families for a single rod, rod bipolar, AII amacrine, and ON ganglion cell. Horizontal scale bars are 200 ms in each panel; vertical scale bars are 200 pA for the ganglion cell, 100 pA for the AII amacrine cell, 50 pA for the rod bipolar cell, and 5 pA for the rod. Bottom: Stimulus–response relations from flash families as in the top panels. Data from A. P. Sampath and Felice Dunn.

conditions is a disaster as it inextricably mixes signal and noise. A better strategy is to average only after first making a selection of signals from those people of potential interest (based on some prior criteria – for example, how loudly they are yelling) and discarding signals from the rest. This is the strategy the retinal readout adopts: the rod bipolar pathway selectively retains signals from those rods likely to be generating single-photon responses and discards noise from the remaining rods (Field, G. D. and Rieke, F., 2002b). This selective retention of signals of interest can dramatically improve visual sensitivity. To be effective, such a selection must occur prior to mixing of rod signals – that is, in the transmission of signals from the rod to the rod bipolar cell dendrite.

Responses likely to be generated by photon absorption can be selected by applying a threshold to the rod signals. Evidence for a thresholding nonlinearity at the rod-to-rod bipolar synapse comes from comparing light responses of rods and rod bipolar cells (Field, G. D. and Rieke, F., 2002b). Rods respond linearly to flashes producing up to ~5 Rh^* – for example, the rod response doubles when the flash strength is doubled (Baylor, D. A. *et al.*, 1984; Nakatani, K. *et al.*, 1991). Figure 10(a) illustrates this well-known linearity of the rod signals. The inset shows a flash family recorded from a mouse rod, with the thick traces showing responses to flashes producing <6 Rh^* on average. The amplitudes of the responses to dim flashes scale linearly with flash strength, as shown in the main panel of Figure 10(a). Rod bipolar cell responses depend supralinearly on flash strength for flashes producing 0.5–1 Rh^* per rod. For example, the response more than doubles when the flash strength is doubled (Figure 10(b)). This supralinear behavior can be explained if a small single-photon response in the rod fails to exceed a threshold required to generate a response in the rod bipolar, while a large single-photon response or a response to two photons exceeds threshold and is faithfully transmitted. Such a thresholding causes responses to flashes in which few or no rods absorb more than one photon to be attenuated relative to responses to flashes that produce a higher probability of two or more photon absorptions in single rods. As expected, this nonlinear transfer of signals eliminates much of the rod's continuous noise, so that the rod bipolar dark noise is much less than expected from a linear summation of ~20 rod inputs (Field, G. D. and Rieke, F., 2002b). Modeling of the rod-to-rod bipolar synapse (Berntson, A. *et al.*, 2004) and electroretinograms (Saszik, S. M. *et al.*, 2002) provide further evidence for a thresholding nonlinearity, although the fraction of excluded single-photon responses is not agreed upon.

In principle, several aspects of synaptic transmission could produce such a nonlinearity. In fact it appears to be produced by saturation within the second

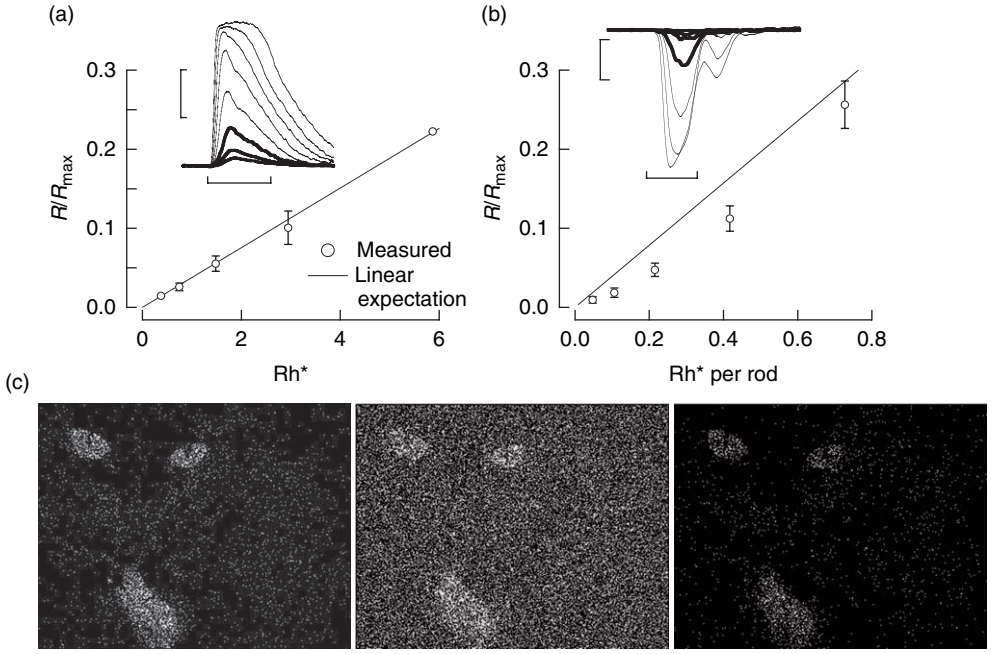

Figure 10 Thresholding nonlinearity at the rod-to-rod bipolar synapse. (a) Linearity of rod responses to dim flashes. Inset superimposes average rod responses to flashes producing an average of 0.75 to 100 Rh^*. Horizontal scale bar is 500 ms, vertical scale bar is 5 pA. (b) Supralinearity of rod bipolar responses. Inset superimposes average responses to flashes producing an average of 0.25 to 16 Rh^* per rod. Horizontal scale bar is 200 ms, vertical scale bar is 50 pA. (c) Simulation of effects of thresholding nonlinearity. (Left panel) Simulation of signals in rod array for an image producing a mean of 0.1 Rh^* per rod. (Right panel) The same image passed through a thresholding nonlinearity that discards all responses with an amplitude smaller than the mean single-photon response. Data from Greg Field and A. P. Sampath.

messenger cascade linking glutamate receptors to ion channels in the rod bipolar dendrite (Sampath, A. P. and Rieke, F., 2004). As a consequence, at most 1–2% of the transduction channels in the rod bipolar dendrites are open in the dark. This is an advantageous location. A nonlinearity located any later (e.g., by voltage-dependent conductances in the bipolar soma) would be ineffective in selectively retaining signals from rods generating single-photon responses because signals from different rods would already be mixed. A nonlinearity located earlier could fail to eliminate the noise generated within the bipolar – for example, noise inherent in the spontaneous activity of components of the rod bipolar transduction cascade, including channel noise.

Discarding a fraction of the rod's single-photon responses in transmission to the rod bipolar cell seems like a poor strategy to optimize sensitivity at low light levels. But this intuition is wrong. The likelihood that a given rod response is due to photon absorption as opposed to rod noise depends on light level. This dependence can be appreciated by considering the case of no incident light – in which case all rod responses are attributable to rod noise. In this extreme case, optimal processing means ignoring the rod signals altogether and instead relying on the prior information that no light is present – that is, under these conditions an optimally positioned thresholding nonlinearity should eliminate all rod responses. The low probability of photon absorption near absolute visual threshold introduces a strong prior probability (99.9% at 0.001 Rh^* per rod) that a rod is generating noise; the only single-photon responses that should be retained have an amplitude sufficiently large to overcome this prior probability because the likelihood that rod dark noise generates fluctuations of this amplitude is even smaller (i.e., less than 0.1% at 0.001 Rh^* per rod). This is analogous to seeing someone who looks like the president at your local supermarket. You have a strong bias that this is an unlikely event, and overcoming that bias would require substantial evidence (e.g., he installs wire taps in the supermarket intercom).

Figure 10(c) illustrates the effect of a thresholding nonlinearity on the fidelity of images in the rod array. The left panel shows a simulated pattern of photon

absorptions for an image producing an average of 0.05 Rh^* per rod. The middle panel simulates the resulting responses in the rod array – that is, with rod noise added. The right panel shows the effect of passing the rod responses through a thresholding nonlinearity that discards half of the rod's single--photon responses. The thresholding selectively preserves light signals in the rod array while discarding noise and hence substantially improves the fidelity of the image at the cost of eliminating half of the original responses. The impact of the thresholding nonlinearity on signal fidelity increases as light levels decrease; at light levels near absolute visual threshold (~0.0001 Rh^* per rod per integration time), the thresholding nonlinearity improves the signal-to-noise ratio of signals in the rod array by more than a factor of 100 (Field, G. D. and Rieke, F., 2002b).

An essentially identical issue arises at the synapse between rod bipolar and AII amacrine cells. AII amacrines receive converging input from the rod bipolars, and at visual threshold a small fraction (0.1–0.2% at 0.0001 Rh^* per rod per integration time) of the rod bipolars generate responses to photons absorbed within the pool of rods from which they receive input during the rod integration time. Meanwhile all of the rod bipolar cells generate intrinsic noise, which, if not removed before reaching the AII amacrine cell, could swamp the light responses. Thus a nonlinearity at the synapse between rod bipolar cells and AII amacrine cells could serve to remove noise intrinsic to the rod bipolar and faithfully transmit single-photon responses. This possibility has not been tested to date. In general, a repeated theme of nonlinear processing prior to convergence could enable sparse signals to be effectively transmitted through a neural circuit while rejecting noise introduced at each processing stage.

1.18.4.2 Representing and Extracting Temporal Information

Single-photon responses generated by the rods are slow – with a time-to-peak of ~200 ms and a duration of ~500 ms in mammalian rods (see Figure 7). Many critical computations, such as motion detection, rely on determining the relative timing of light inputs and thus require extracting temporal information from the rod responses. In the absence of noise, the low-pass temporal filtering provided by the rod phototransduction cascade could be undone to recover the exact times of photon absorptions. Rod noise makes recovery of the exact photon absorption times impossible, but still permits extraction of temporal information finer than the duration of the rod responses (Figure 7). This section summarizes what is known about how the retinal circuitry extracts temporal information from the rod responses and how accurately retinal ganglion cells represent this information.

1.18.4.3 Extraction

The rod-mediated dim flash responses of both amphibian (Ashmore, J. F. and Falk, G. 1980; Schnapf, J. L. and Copenhagen, D. R., 1982) and mammalian (Berntson, A. and Taylor, W. R., 2000; Euler, T. and Masland, R. H., 2000; Field, G. D. and Rieke, F., 2002b) bipolar cells are considerably briefer than those of the rods themselves. For example, Figure 11(a) compares dim flash responses of mouse rods and rod bipolar cells. The rod bipolar response reaches peak and recovers much more quickly than the rod response; in fact the bipolar response is nearly complete when the rod response reaches peak. The synaptic inputs to retinal ganglion cells evoked by dim flashes have kinetics similar to those of the rod bipolar responses (Field, G. D. *et al.*, 2005). Thus the synapse between rods and rod bipolar cells is a key determinant of the kinetics of rod-mediated signals in the retina.

The speeding of rod responses in transmission to rod bipolar cells has several consequences for the encoding of single-photon responses. First, the time of photon absorption is represented more explicitly in the briefer bipolar response as the synapse undoes some of the slowness of the rod transduction process. Second, the synapse transmits the most reliable part of the rod response – the rising phase – while suppressing the more variable recovery phase. Figure 11(b) illustrates the variability in the rod single-photon responses by superimposing 20 isolated single-photon responses and 20 responses to zero absorbed photons. Variability is small until roughly the response peak and then increases during the response recovery (Rieke, F. and Baylor, D. A., 1998a; 1998b; Field, G. D. and Rieke, F., 2002a). The increased late variability poses a particular threat for encoding the time course of continuous inputs, as the noise in the falling phase of the response to one photon absorption could obscure the response to a subsequent absorption. At low light levels, photons arrive rarely at a single rod, and hence the resulting responses are unlikely to overlap in time. However,

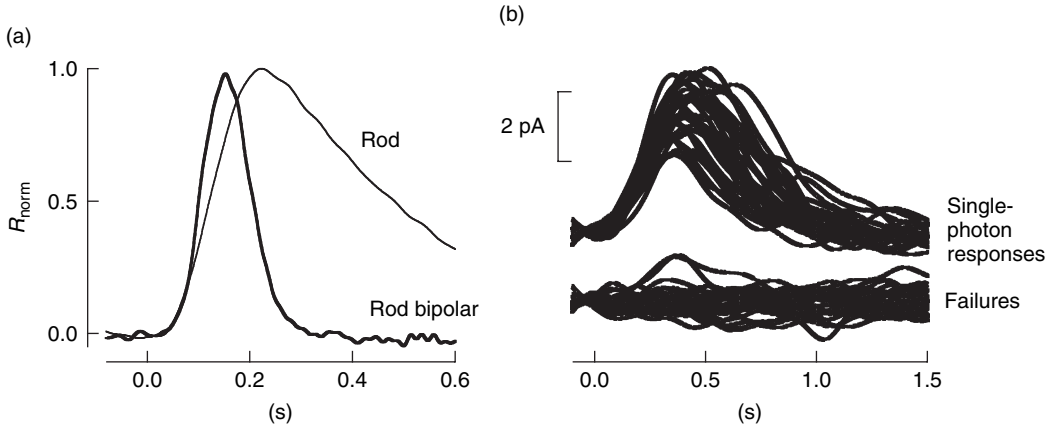

Figure 11 Extraction of temporal information in rod-to-rod bipolar signal transfer. (a) Average rod (thin trace) and rod bipolar (thick trace) responses to a weak flash. Responses have been normalized to facilitate comparison of their kinetics. (b) Variability of the single-photon responses is low during initial part of the response and increases during the response recovery. The top traces show 20 isolated single-photon responses from a mouse rod. The bottom traces show 20 isolated responses to 0 absorbed photons. Data from A. P. Sampath and Thuy Doan.

single-photon responses will often overlap in downstream cells that receive converging inputs from many rods. Eliminating or suppressing the falling phase of the rod's single-photon response in transmission to rod bipolar cells minimizes the impact of such temporal overlap on the fidelity with which continuous inputs are encoded.

In amphibians, the change in kinetics of rod-mediated responses in transmission to bipolar cells has been given a more solid theoretical and mechanistic basis. How should the rod responses be processed to estimate the photon absorption times? Low temporal frequencies have intrinsically lower temporal resolution and thus should be attenuated. High temporal frequencies are dominated by continuous noise, making these frequencies unreliable indicators of light inputs. Thus inferring temporal properties of the input signals involve filtering the rod responses with a band-pass filter matched to the signal and noise properties of the rod. This line of reasoning leads to a parameter-free prediction of the kinetics of the bipolar responses based solely on the measured rod signal and noise (Bialek, W. and Owen, W. G., 1990; Rieke, F. *et al.*, 1991). The measured bipolar responses are in good agreement with these predictions, indicating that the kinetics of signal transfer is matched to the temporal characteristics of the rod signal and noise.

Paired recordings from rods and synaptically connected bipolar cells in salamander retina directly showed the attenuation of low and high temporal frequencies at the rod-to-bipolar synapse (Armstrong-Gold, C. E. and Rieke, F., 2003). Thus modulations of the rod voltage at frequencies below 1 Hz or above 4 Hz were much less effective in producing postsynaptic responses than frequencies of 2–3 Hz. The attenuation of low temporal frequencies was apparent in the rate of excitatory postsynaptic currents measured in OFF bipolar cells, indicating that at least this part of the synaptic filtering was generated by presynaptic mechanisms.

1.18.4.4 Representation

How precisely do retinal ganglion cells encode changes in the photon absorption rate in the rods? Because they have access to signals from many rods, ganglion cells can in principle encode considerably more precise temporal information than individual rods. Two experimental approaches indicate that this is indeed the case.

One approach to estimate temporal precision is to determine the ability to discriminate between two possible flash times based on a single example of the ganglion cell spike response. Many examples of responses at the early and late time are used to learn how the ganglion cell responses differ between the two flash times. Then the most likely flash time is determined for a single response not used in the learning process. This process is repeated many times for different test responses and the percentage of correct discrimination determined. Temporal precision is defined as the time separation between the possible flash times resulting in a criterion level of

performance – for example, 75% correct discrimination. Not surprisingly, temporal precision in this discrimination task improves as flash strength increases. This dependence on flash strength means that it is not possible to give a single measure of temporal precision, unlike detection threshold, which lends itself to a unique definition. Nonetheless, the responses of both salamander and primate ganglion cells encode the flash time with a precision much finer than the duration of the rod response across a wide range of flash strengths (Chichilnisky, E. J. and Rieke, F., 2005; Field, G. D. *et al.*, 2003 Neurosciences Abstract; Uzzell *et al.*, 2003 Neurosciences Abstract). In both cases, flashes producing less than one Rh^* per rod (less than 0.01 Rh^* per rod in primate) are encoded with a temporal precision 10–30 times finer than the duration of the rod response.

A second approach to estimate temporal precision is to measure the similarity of different responses to a repeated stimulus. Figure 12 shows examples of the spike responses of a mouse ganglion cell to a repeated random stimulus with a mean intensity of 2.5 Rh^* per rod per second and a contrast of 50%. Each vertical tick in Figure 12(b) represents a single action potential, and each row shows the response to a single repetition of the stimulus. Figure 12(a) shows the average response of a single rod to the same stimulus. Figure 12(c) shows a short section of both rod and ganglion cell responses. The ganglion cell responses show strong similarity from one trial to the next; in particular they show similarity on a timescale much shorter than the modulations in the rod response, indicating that the temporal precision is much greater than might be expected from the slow rod inputs. Indeed, the standard deviation of the first spike time in bursts such as that in the bottom panel averages ~5 ms (range across events 2–10 ms) for these stimuli, ~3% of the correlation time of the rod response.

The temporal precision of ganglion cell responses is one of several examples of acuity beyond the naive

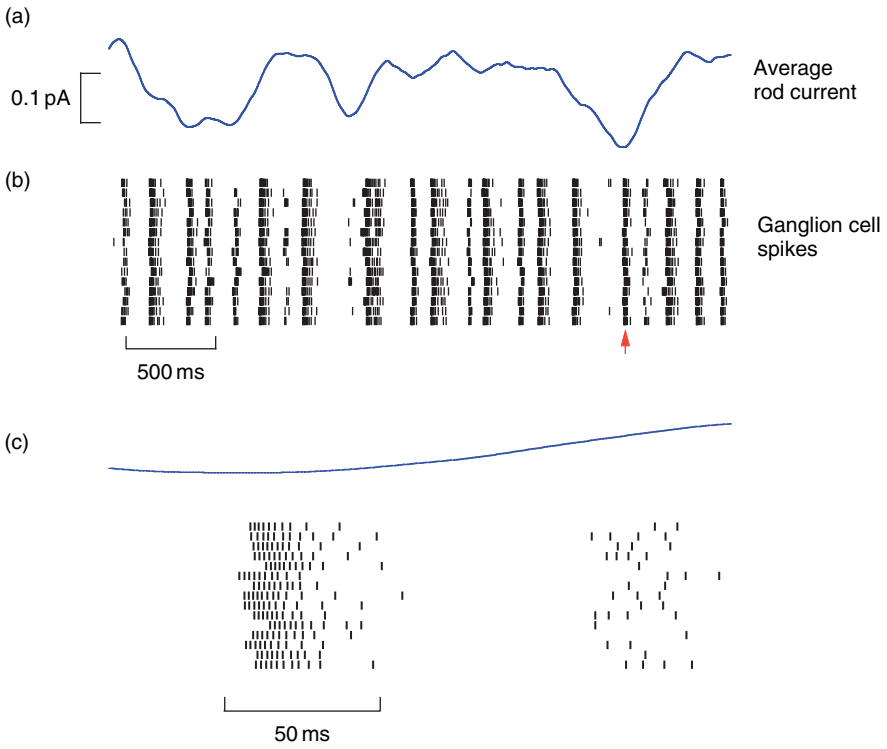

Figure 12 Temporal precision of ganglion cell responses to a repeated random stimulus with a mean of 2.5 Rh^* per rod per second. (a) Estimated average rod response to this stimulus. The rod response was generated by convolving the measured rod single-photon response with the random stimulus. Direct measurement of the average rod response is difficult because the low light level and the resulting large Poisson fluctuations in photon absorption would require averaging thousands of trials. (b) Several individual spike responses of an ON retinal ganglion cell to the same stimulus. (c) Section of rod (smooth line) and ganglion cells responses on expanded timescale. The burst of spikes on the left is marked by the red arrow in panel (b). Data from Gabe Murphy.

limits set by the sampling properties of the receptors. Other familiar examples are chromatic sensitivity, which exceeds expectations from the coarse spectral sensitivities of the cone photoreceptors, and spatial acuity, which exceeds expectations from the spacing between foveal cones. In each such instance, the true limit to acuity is set by the signal and noise properties of the receptor responses. We have an incomplete picture, however, of how effectively the retinal readout exploits the low noise of the rod signals to extract and represent temporal information – for example, how the temporal precision of retinal ganglion cells compares to that of the rods from which they receive input.

1.18.4.5 Low Noise

The high sensitivity of dark-adapted vision requires that noise introduced in each step of retinal processing is either small or is removed by subsequent processing. Two issues make the impact of synaptic noise (i.e., fluctuations in transmitter release or in the generation of postsynaptic currents) of particular importance at the rod-to-rod bipolar synapse. First, synaptic noise makes the task of separating single-photon responses from noise in the rod array more difficult; thus synaptic noise is an important factor in determining how much a thresholding nonlinearity at the rod-to-rod bipolar synapse can improve the fidelity of rod-mediated signals and in determining the best position of such a nonlinearity. Second, the presynaptic signal at this synapse is only ~1 mV (Schneeweis, D. M. and Schnapf, J. L., 1995), making reliable transmission challenging in the face of the expected statistical fluctuations in transmitter release.

Photon absorption produces a reduction or a pause in the ongoing transmitter release by the rod. Random pauses or slowing in release due to statistical fluctuations will mimic true photon events, producing a source of noise potentially limiting the visual sensitivity (Falk, G. and Fatt P., 1972). Rao-Mirotznik R. *et al.* (1998) argued that mammalian rods must maintain a dark release rate of at least $100\,s^{-1}$ to ensure that random pauses in release occur less often than thermal isomerization of rhodopsin in the rod outer segment. Their argument is based on two untested assumptions: (1) statistical fluctuations in release obey Poisson statistics and (2) release is completely suppressed for ~100 ms during the single-photon response. With these assumptions, dark release rates lower than $100\,s^{-1}$ lead to an unacceptably high rate of random, 100-ms pauses in release that mimic true single-photon responses.

Schein S. and Ahmad K. M. (2005; 2006) analyzed models for the rod output synapse that relax both of these assumptions. In particular, they explored how synaptic noise is affected by sub-Poisson variability in the release process and by partial rather than complete reductions in the release rate during the single-photon response. They argue that the reduction in release rate during the single-photon response is likely ~20% based on the voltage dependence of the rod Ca^2 channels and the ~1 mV hyperpolarization during the single-photon response. With this smaller signal, synaptic noise could be kept acceptably low for dark release rates near $100\,s^{-1}$, provided the release process is much more regular than a Poisson process. Such regularity in release could be produced, for example, by refractoriness at vesicle fusion sites or another process that effectively times the intervals between vesicle release events.

The above theoretical arguments focus on the criterion that synaptic noise introduces false photon-like noise events at a rate not higher than spontaneous rhodopsin activation. This criterion ensures that the impact of synaptic noise on the detection of dim lights is not greater than discrete noise in the rod outer segment currents. Although this is a convenient criterion, it is not unique. First, the comparison of rod noise with behavior or with retinal ganglion cell responses leaves open the possibility that significant noise is introduced in the retinal circuitry (see Section 1.18.2). This could relax the requirement on low noise at the synapse, though probably not enough to be consistent with Poisson fluctuations in release. Second, there is fortunately much more to vision than detecting the presence or the absence of dim lights. For example, as described above, rods and ganglion cells encode the timing of light inputs with high precision – a precision much finer than the ~100 ms integration times assumed for the studies described above. Maintaining sufficiently low synaptic noise to preserve information about the times of photon absorption would appear to pose a stringent requirement on the statistics of transmitter release.

1.18.5 Summary

The ability of human observers to detect the absorption of a few photons and the resulting activation of a few rhodopsin molecules is one of several examples

in which sensory performance approaches fundamental limits (reviewed by Bialek, W., 1987). Thus pheromone receptors can detect the binding of a few molecules to the receptors on their surface membrane (Leinders-Zufall, T. *et al.*, 2000), chemotactic bacteria can count molecules bound to receptors on their surface (Berg, H. C. and Purcell, E. M., 1977), and auditory hair cells can sense movements of their stereocilia less than the diameter of a hydrogen atom. These observations about the fidelity of sensory encoding provide a clear framework for studying how these systems work; they help pose precise questions, they provide a natural benchmark against which to evaluate our understanding, and they suggest that predictive, theoretical approaches based on optimization may be relevant. This line of reasoning has helped uncover how elegantly suited the rod photoreceptors are for the task of detecting incident photons (reviewed by Rieke, F. and Baylor, D. A., 1998a; 1998b; Burns, M. E. and Baylor, D. A., 2001). The challenges facing the retinal readout of the rod signals are no less daunting than those facing the rods themselves. We know much less, however, about how these challenges are met.

Acknowledgments

I thank Thuy Doan, Felice Dunn, Gabe Murphy, and Barry Wark for helpful comments and Thuy Doan, Felice Dunn, Greg Field, A. P. Sampath, and Gabe Murphy for experimental data for many of the figures. Support was provided by the NIH (EY-11850) and Howard Hughes Medical Institute.

Glossary

direction-selective ganglion cell Certain type of retinal ganglion cell that codes the direction of image motion within its receptive field with its spike response.

direction selectivity/discrimination The ability of a neuronal network, a single neuron, or a subcellular compartment to detect and signal the direction of image motion.

global motion Motion of the whole visual field, as for example caused by head or body motion.

local motion Motion of an object relative to the background.

nonlinearity The behavior of a nonlinear system cannot be described as the sum of its parts.

null direction Direction of motion in which the response of a direction-selective cell is minimal.

preferred direction Direction of motion in which the response of a direction-selective cell is maximal.

starburst amacrine cell Retinal interneuron with a characteristic, radially symmetrical dendritic morphology that functionally participates in the propagation of Ca^{2+} waves in the developing retina and in the generation of direction selectivity in the mature retina. The synonym cholinergic amacrine cell is imprecise because other cholinergic amacrine cells exist in the retinas of at least some species.

1.19.1 Direction-Selective Ganglion Cells

Most of what we know about retinal direction selectivity (DS) comes from studies on rabbit retina, where direction-selective ganglion cells (DSGCs) (Figure 1(a)) were described first (Barlow, H. B. and Hill, R. M., 1963). Morphologically equivalent ganglion cell types have been found in a number of vertebrates (reviewed in Vaney, D. I. *et al.*, 2001), including primates (Yamada, E. S. *et al.*, 2005). Physiological recordings of DSGCs in species other than rabbits are rare; however, in cases where measurements were made, such as in mice (Weng, S. *et al.*, 2005) or turtles (Marchiafava, P. L., 1979; Borg-Graham, L. J., 2001), very similar functional properties have been found, suggesting the DS circuit to be present in all vertebrate retinas.

Two types of DSGCs can be distinguished (Figure 1(b); reviewed in Vaney, D. I. *et al.*, 2001; Taylor, W. R. and Vaney, D. I., 2003; Masland, R. H., 2004). In the rabbit, one type is the ON DSGC,

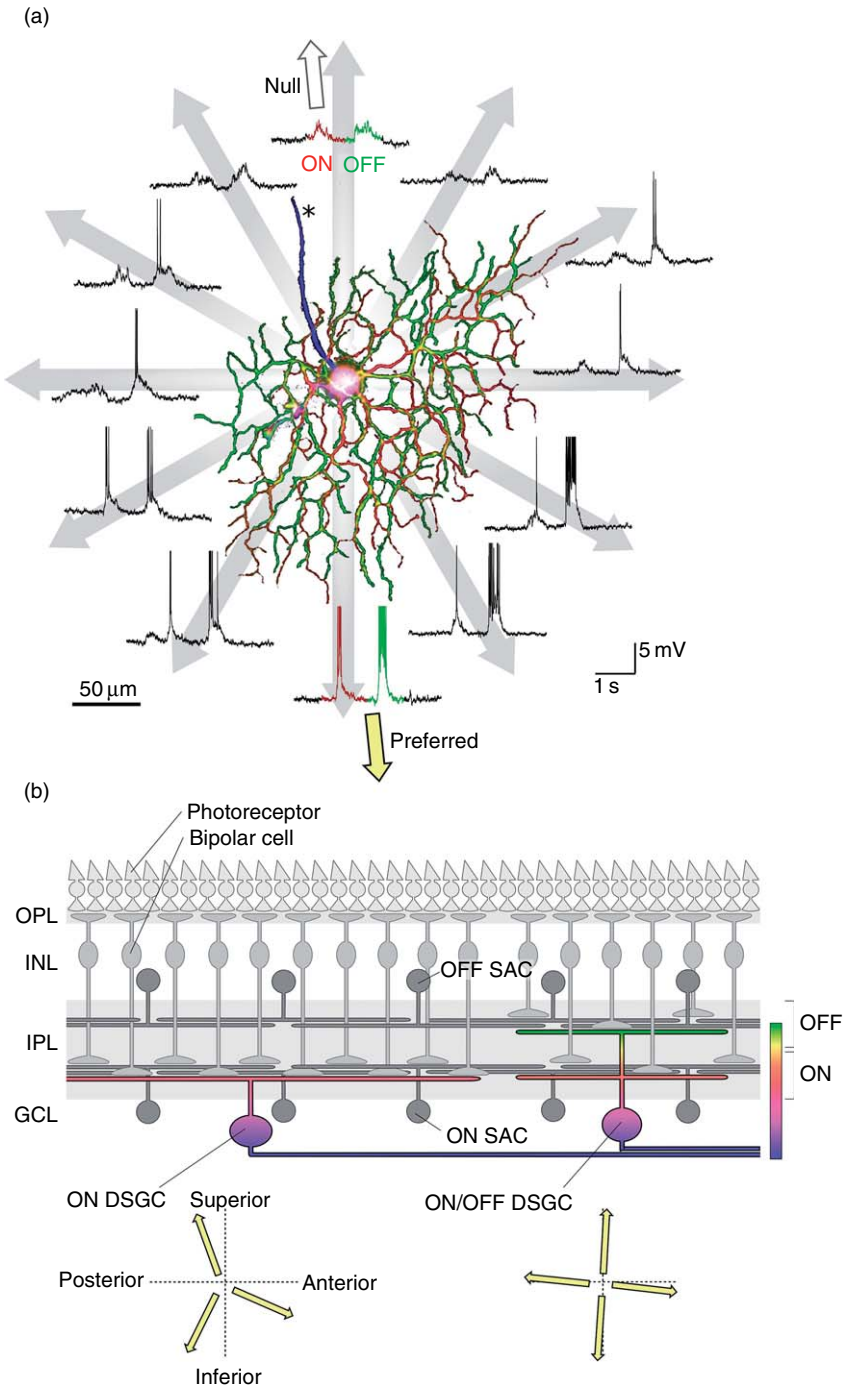

Figure 1 Direction-selective ganglion cells (DSGCs). (a) ON/OFF DSGC filled with fluorescent dye by microinjection (flat-mounted rabbit retina; pseudocolor codes for retinal depth). The cell is bistratified with dendrites ramifying in the ON (red) and OFF sublamina (green) of the inner plexiform layer (IPL). Axon (blue) is marked by asterisk. Electrical responses to a bright bar (300 μm wide, 1000 μm long) moving in 12 different directions on a dark background are shown. (b) Schematic diagram of a retinal cross-section. Only cells known to be directly involved in the DS circuitry are depicted; ON and ON/OFF DSGCs are color-coded for retinal depth (see (a)). Bottom: Preferred directions of the two types of DSGCs. GCL, ganglion cell layer; INL, inner nuclear layer; OPL, outer plexiform layer; SAC, starburst amacrine cell. Adapted from Oyster, C. W. and Barlow, H. B. 1967. Direction-selective units in rabbit retina: distribution of preferred directions. Science 155, 841–842.

which makes up less than 1% of all ganglion cells and is mainly found in the vicinity of the visual streak. Its monostratified dendritic arbor is in the inner half (ON sublamina) of the inner plexiform layer (IPL) and has a diameter between 300 and 800 µm. ON DSGCs respond to bright stimuli moving on a darker background, are sensitive to low-velocity motion (up to few degrees per second; $1^\circ \approx 150\,\mu m$ on an adult rabbit's retina), and comprise three functional subtypes, each preferring a distinct direction of motion (Figure 1(b), bottom). The second type is the ON/OFF DSGC, which accounts for more than 10% of all ganglion cells in rabbits and is found at all retinal eccentricities. It is bistratified, with one dendritic arborization in the OFF and the other in the ON sublamina. Tapping into both the ON and the OFF pathways allows this type of DSGC to detect objects that are brighter as well as objects that are darker than the background. The two arborizations, which are less than half the diameter of those of ON DSGCs, are not necessarily coextensive and can differ in size and shape (Oyster, C. W. *et al.*, 1993; Vaney, D. I., 1994), suggesting that the ON and OFF DS circuits work independently. ON/OFF DSGCs prefer higher velocities (up to $20^\circ\,s^{-1}$) than do the ON type; their functional subtypes prefer one of four different motion directions (Figure 1(b), bottom).

Each of the seven functional DSGC subtypes tiles the retinal surface in a territorial manner with little overlap (ON/OFF: Vaney, D. I., 1994; Amthor, F. R. and Oyster, C. W., 1995; ON: Buhl, E. H. and Peichl, L., 1986), such that information for any of the different preferred directions of motion is thought to be available at every retinal location (see Section 1.19.5). Since most research has focused on the ON/OFF DSGCs, in the following the term DSGC will refer to this type unless indicated otherwise.

1.19.2 The Circuitry Underlying Retinal Direction Selectivity

In one of the first models of retinal DS (Barlow, H. B. *et al.*, 1964), it was proposed that a DSGC receives delayed (or long-lasting) inhibitory input preferentially from interneurons displaced to the null side of its receptive field. An object moving in null direction would trigger this inhibition, which cancels out excitation by the object entering the DSGC's receptive field. While this model – in its original form – is not consistent with what we know today about the DS circuitry, it pointed out two of the three key properties of any detection circuit (Reichardt, W., 1961; reviewed in Borst, A. and Egelhaaf, M., 1989): a time delay (discussed in Section 1.19.3) and spatial asymmetry in the wiring. The third property is nonlinearity (see Section 1.19.3), which was not explicitly included in the original model (see also Masland, R. H., 2004).

There is ample functional evidence for asymmetrical wiring of the DS circuitry. For example, the preferred side of the DSGC's receptive field contains a zone in which motion elicits equivalent spiking responses for both preferred- and null-direction motion (Barlow, H. B. and Levick, W. R., 1965). The presence of this nondiscriminating zone indicates that synaptic input to DSGCs cannot be spatially symmetrical. Furthermore, recordings of pairs of DSGCs and neighboring starburst amacrine cells (SACs; see Section 1.19.2.2) revealed that DSGCs receive inhibitory inputs only from SACs located on the DSGCs' null side (Fried, S. I. *et al.*, 2002), indicating that DSGCs receive spatially offset inhibition. An anatomical correlate for such asymmetrical connectivity, however, has not yet been identified. In fact, it seems to be impossible to predict the preferred motion direction of a DSGC from its overall morphology (Amthor, F. R. *et al.*, 1984; Oyster, C. W. *et al.*, 1993; Yang, G. and Masland, R. H., 1994) or the distribution pattern of synaptic inputs (Jeon, C. J. *et al.*, 2002).

1.19.2.1 Pre- or Postsynaptic

The question whether DS is computed postsynaptically, that is, from non-DS excitatory and inhibitory inputs in the DSGCs themselves, or presynaptic to the DSGCs led to a long controversy (reviewed in Taylor, W. R. and Vaney, D. I., 2003; Masland, R. H., 2004). Progress toward answering this question has been made recently, when in a series of patch-clamp studies the synaptic inputs to DSGCs were found to be already direction-selective (Borg-Graham, L. J., 2001; Fried, S. I. *et al.*, 2002; Taylor, W. R. and Vaney, D. I., 2002). Stimuli moving in the preferred direction elicit more excitation and less inhibition in the DSGCs than stimuli moving in the null direction. Hence, motion direction is, at least in part, computed in interneurons presynaptic to the DSGCs.

1.19.2.2 Starburst Amacrine Cells

One type of interneuron that provides massive synaptic input to DSGCs and had been suggested to

participate in the computation of retinal DS in early studies (Masland, R. H. *et al.*, 1984a; Vaney, D. I. *et al.*, 1989; Borg-Graham, L. J. and Grzywacz, N. M., 1992) is the SAC (Figure 2(a); Masland, R. H. and Mills, J. W., 1979; Famiglietti, E. V., 1983).

SACs release two types of transmitters (Masland, R. H. *et al.*, 1984b; Brecha, N. *et al.*, 1988; Vaney, D. I. and Young, H. M., 1988): gamma-aminobutyric acid (GABA) and acetylcholine (ACh). There are OFF and ON SAC subtypes (Figure 2(c)), which – apart from their opposite response polarity – are considered functionally equivalent. The dendrites of both subtypes costratify with the respective arborizations of the ON/OFF DSGCs; the ON SAC also costratifies with the ON DSGC's arborization. Unlike most retinal neurons, SACs display extensive dendritic overlap (Tauchi, M. and Masland, R. H., 1984) and thus could provide input dedicated to each functional subtype of DSGC (see also Section 1.19.3.1). SACs feature a characteristic morphology (Famiglietti, E.

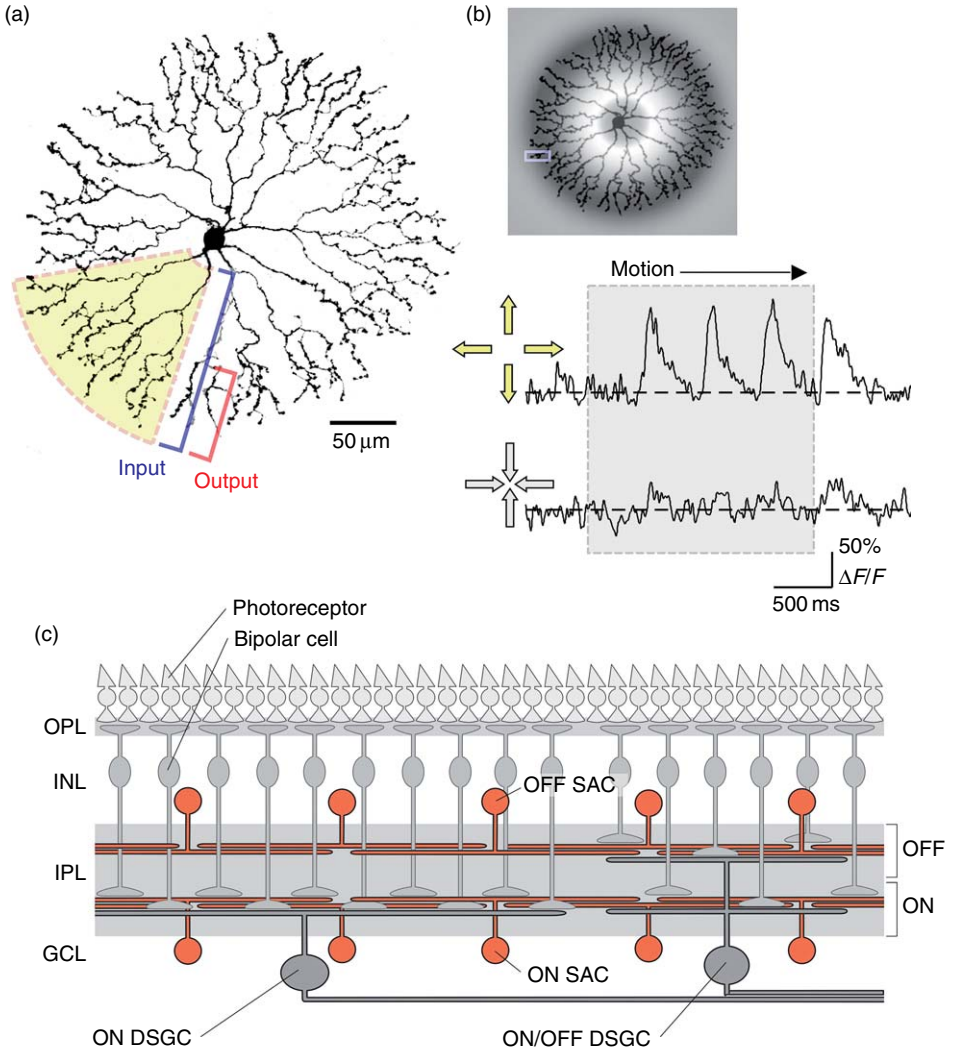

Figure 2 Starburst amacrine cells (SACs). (a) ON SAC filled with fluorescent Ca^{2+} indicator dye by microinjection (flat-mounted rabbit retina). Example for wedge-shaped dendritic sector (yellow) and radial distribution of input (blue) and output synapses (red) are indicated. (b) Top: Schematic representation of SAC with circular wave stimulus. *Bottom*: Dendritic Ca^{2+} response, recorded by two-photon fluorescence microscopy (Denk, W. *et al.*, 1990; light-blue box on cell image marks Ca^{2+}-imaging site), for centrifugal-motion (from soma to dendritic tips; upper trace) and centripetal-motion (from dendritic tips to soma; lower trace) of the circular wave stimulus. (c) Schematic diagram of a retinal cross-section; ON and OFF SACs are indicated (orange). DGSC, direction-selective ganglion cell; GCL, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; OPL, outer plexiform layer.

V., 1983; Tauchi, M. and Masland, R. H., 1984; Vaney, D. I., 1984), which is well conserved across species: four to six primary dendrites (sectors, Figure 2(a)) radiate from the soma before dividing into smaller branches. Each sector, unlike the whole cell, is strongly polarized anatomically and physiologically. Synaptic inputs from both bipolar and amacrine cells cover the whole length of the dendrite, but outputs are restricted to the distal part, which is decorated with bead-like varicosities (Famiglietti, E. V., 1991). Delayed rectifier K^+ channels are concentrated on the soma and proximal dendrite (Ozaita, A. *et al.*, 2004), which, in combination with the peculiar morphology, leads to an electrical isolation of the sectors from each other (Miller, R. F. and Bloomfield, S. A., 1983; Velte, T. J. and Miller, R. F., 1997). Hence, the sectors can be seen as largely independent processing units (Masland, R. H. *et al.*, 1984a; Vaney, D. I., 1990; Borg-Graham, L. J. and Grzywacz, N. M., 1992; Poznanski, R. R., 1992; Euler, T. *et al.*, 2002).

Massive ablation of SACs results in a selective loss of retinal DS (Yoshida, K. *et al.*, 2001; Amthor, F. R. *et al.*, 2002), and thus, it is commonly agreed that SACs are essential for DS. Optical measurements of light-stimulus-evoked Ca^{2+} signals (Denk, W. and Detwiler, P. B., 1999) in the dendrites of SACs suggest that these cells contribute directly to the directionally tuned input seen in DSGCs (Euler, T. *et al.*, 2002). These experiments showed that visual stimuli moving from the soma to the dendritic tips elicit larger Ca^{2+} responses in the dendritic tips than do those moving from the tips to the soma (Figure 2(b); Euler, T. *et al.*, 2002). That SACs' output synapses are located in the distal dendrites (Famiglietti, E. V., 1991) and transmitter release from SACs is Ca^{2+}-dependent (O'Malley, D. M. *et al.*, 1992; Zheng, J. J. *et al.*, 2004) is consistent with SACs providing directionally tuned synaptic output.

1.19.2.3 Pathways

The robust direction discrimination seen in DSGCs over wide contrast (Merwine, D. K. *et al.*, 1998) and velocity ranges (Oyster, C. W. *et al.*, 1972; Wyatt, H. J. and Daw, N. W., 1975) suggests that the underlying circuitry relies on multiple pathways and computational mechanisms (see also Section 1.19.3) to generate and enhance retinal DS signals (reviewed in Fried, S. I. *et al.*, 2005). For example, dendritic processing in DSGCs was found to contribute to DS by further sharpening directional tuning of synaptic inputs (Oesch, N. *et al.*, 2005). Support for multiple pathways also comes from the fact that both inhibitory and excitatory inputs to DSGCs are direction-selective (see Section 1.19.2.1).

1.19.2.3.1 Direction-Selective inhibition

Pharmacological block of $GABA_A$ receptors abolishes directional responses in DSGCs but leaves their light responsiveness intact (Wyatt, H. J. and Daw, N. W., 1976; Caldwell, J. H. *et al.*, 1978; Massey, S. C. *et al.*, 1997), indicating that the direction-selective inhibition of DSGCs is mediated by GABA. This GABAergic input is at least partially provided by SACs (see Section 1.19.2.2). DSGCs also receive inhibitory input from other, not identified amacrine cells (reviewed in Dacheux, R. F. *et al.*, 2003), which may provide additional DS inhibition. Unequivocal evidence for this, however, is lacking.

1.19.2.3.2 Direction-Selective excitation

DSGCs receive excitatory glutamatergic input from bipolar cells (Brandon, C., 1987; Famiglietti, E. V., 1991), which is directionally tuned (Fried, S. I. *et al.*, 2005). The underlying circuitry has not yet been identified. It is conceivable, though, that such tuning could arise from direction-dependent suppression of bipolar cell output by amacrine cells. SACs are a possibility, although SACs' output synapses onto bipolar cells appear to be rather sparse (Famiglietti, E. V., 1991; Yamada, E. S. *et al.*, 2003).

Since DSGCs possess ACh receptors and SACs are considered the main source of ACh in the retina, it is likely that SACs provide DSGCs with cholinergic input (reviewed in Vaney, D. I. *et al.*, 2001). Blocking ACh receptors in the presence of GABA antagonists reduces the DSGCs' response independent of motion direction (Chiao, C. C. and Masland, R. H., 2002), suggesting that cholinergic excitation affects DSGCs symmetrically and provides motion-sensitive but not direction-selective excitation (He, S. and Masland, R. H., 1997). On the other hand, blocking only cholinergic transmission reduces the directional tuning of inhibitory inputs to DSGCs (Fried, S. I. *et al.*, 2005), which may explain the finding that for certain stimuli, such as gratings, cholinergic blockers cause a decrease in ganglion cell DS (Grzywacz, N. M. *et al.*, 1998). Hence, complex interactions between the cholinergic and the GABAergic pathways clearly exist. Nonetheless, the functional role of cholinergic transmission for DS is not yet fully understood.

1.19.3 Retinal Direction Selectivity Computation Mechanism(s)

While a complete model of retinal DS that adequately incorporates the directionally tuned inhibitory and excitatory pathways is still lacking, some of the circuit's features and working principles are well understood. Direction-sensitive signals are generated presynaptic to DSGCs and appear to be enhanced by network interactions at several stages in the DS circuitry. In particular, spatially offset inhibition is a recurrent theme in the retinal DS circuit (discussed in Fried, S. I. *et al.*, 2005). While it is likely that SACs are a major, if not the main, source of DS signals, it is possible that additional DS arises somewhere else in the circuitry. The actual biophysical mechanism(s) by which DS is computed is still a matter of debate (reviewed in Vaney, D. I. *et al.*, 2001; Taylor, W. R. and Vaney, D. I., 2003).

In principle, a mechanism for detecting motion direction requires three key elements: a time delay, spatial asymmetry, and nonlinearity (Hassenstein, B. and Reichardt, W., 1956; Reichardt, W., 1961; reviewed in Borst, A. and Egelhaaf, M., 1989). A correlation-type direction detector, like the one shown in Figure 3, is the basis for most models of retinal DS. Nonetheless, the models differ greatly in the types of neurons recruited or in the biophysical mechanisms employed. The models listed in the following are not necessarily mutually exclusive; some may complement each other.

1.19.3.1 Computations Based on Network Interactions

One class of models is based on network interactions. In these models, nonlinearity is generated through the interaction of excitation and (shunting) inhibition (Koch, C. *et al.*, 1983; Borg-Graham, L. J. and Grzywacz, N. M., 1992). The required time delays are assumed to arise from electrical cable properties and/or synaptic interactions. In many models, the spatially displaced element is the SAC, with its role ranging from computing DS to simply relaying input to DSGCs.

Alternatively, other, not further specified amacrine cells are incorporated into some models. A general problem with this is that most neuron types tile the retina and, thus, are not numerous enough to provide the seven functional subtypes of DSGCs at each retinal location with adequate directional input (reviewed in Vaney, D. I. *et al.*, 2001). The lack of cells could, however, be compensated for by highly localized dendritic processing.

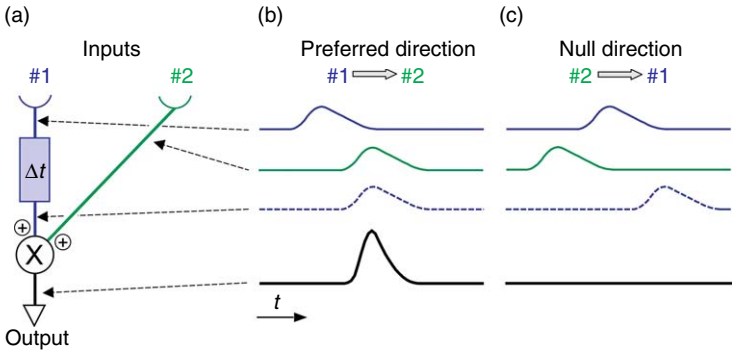

Figure 3 Model of a direction detector. (a) Simplified model of a correlation-type direction detector. This class of detectors was originally deduced from behavioral experiments on visual motion processing in insects (Reichardt, W., 1961). In the variant depicted here, light intensity is measured at two points (#1 and #2) in space, providing two excitatory (+) inputs. After input #1 has been delayed by a time interval (Δt), they are combined by a nonlinear operation (in this case, a multiplication; X). (b, c) Responses to preferred- (b) and null-direction motion (c) measured at different elements in the circuit. Due to the distance between the points of light measurement, the two input signals arrive at different time points (compare upper two traces). For preferred-direction motion (b), this temporal separation is compensated for by the delay applied to input #1 (third trace), such that at the multiplying stage, both inputs coincide (bottom trace). For null-direction motion (c), the temporal sequence of the inputs is reversed; the delay Δt increases the temporal shift between the inputs such that they do not coincide at the multiplying stage. This is just one possible variant of a correlation-type detector. Other variants combine excitatory and inhibitory inputs and/or use a different type of nonlinearity. The fixed time delay, which allows the detection of only a small range of motion velocities, can be replaced by a low-pass filter to broaden the velocity-tuning curve of the detector. (a) Adapted from Borst, A. and Egelhaaf, M. 1989. Principles of visual motion detection. Trends Neurosci. 12, 297–306.

1.19.3.1.1 Starburst cell networks

Ultrastructural (Millar, T. J. and Morgan, I. G., 1987) and functional data (Zheng, J. J. *et al.*, 2004) indicate that SACs form reciprocal synapses. In the mature retina, where GABAergic SAC interactions are prominent, this network has been implicated in the computation of DS (reviewed in Vaney, D. I. *et al.*, 2001). If an SAC is excited, it inhibits its neighbor. This in turn reduces the neighbor's GABA release and in effect enhances the first SAC's response. Such interaction can sharpen the DS difference in neighboring SAC dendrites pointing in opposite directions (Lee, S. and Zhou, Z. J., 2006). Nevertheless, since GABA receptor antagonists do not abolish DS in the dendritic Ca^{2+} signals (Euler, T. *et al.*, 2002) and in somatic voltage responses (Hausselt, S. E. *et al.*, 2007), it is unlikely that GABAergic SAC interactions are essential for dendritic DS in SACs.

1.19.3.2 Computations Based on Intrinsic Properties

The second class of models concentrates on intrinsic properties of SACs (e.g., Barlow, H. B., 1996; Gavrikov, K. E., *et al.*, 2003; Gavrikov, K. E., *et al.*, 2003; 2006; Tukker, J. J. *et al.*, 2004) and/or makes use of the fact that the dendritic sectors of SACs can be viewed as largely independent and polarized computational units (see Section 1.19.2.2). Each of the sectors is thought to code a different preferred direction, responding more strongly to motion from the soma toward the dendritic tips (centrifugal) than to motion from the tips toward the soma (centripetal) (Figures 2(a) and 2(b)).

Passive computational models predict that SAC dendrites generate weak DS signals simply by summation of inputs along the dendrite (reviewed in Tukker, J. J. *et al.*, 2004). Due to summation, motion from the soma to the dendritic tips evokes a larger signal in the dendritic tips, whereas motion from the dendrites to the soma evokes a larger signal in the soma. As the SACs' output synapses are located in the dendritic tips, motion from the soma to the dendritic tips would lead to a larger output signal to DSGCs. In this scenario, the threshold for transmitter release at the output synapse serves as the essential nonlinearity. The DS found in such passive models seems, however, small and too sensitive to stimulus parameters to explain the robust direction discrimination observed in DSGCs. Also, passive models predict a larger electrical signal at the soma for centripetal motion, which contradicts experimental observations (Peters, B. N. and Masland, R. H., 1996; Euler, T. *et al.*, 2002); Gavrikov, K. E., *et al.*, 2003.

To circumvent the deficits of passive models, voltage-gated channels have been incorporated to account for the nonlinearities that are differentially activated depending on the direction of motion (Borg-Graham, L. J. and Grzywacz, N. M., 1992). SACs possess a variety of suitable voltage-gated Ca^{2+} channels (Cohen, E. D., 2001; Kaneda, M. *et al.*, 2007) and possibly Na^{+} channels. Experimental data and modeling suggests that DS in SACs relies on a voltage difference between soma and (depolarized) distal dendrites that provides spatial asymmetry and leads to stronger activation of voltage-gated channels for motion from the soma toward the dendritic tips than for motion in opposite direction (Hausselt, S. E. *et al.*, 2007).

1.19.4 Developmental Aspects

So far no conclusive explanation of how the retinal DS circuitry arises during development has been presented. It is known, though, that this process does not require visual input, because the dendritic architecture of DSGCs and SACs is established before the retina responds to visual stimuli (Wong, R. O. and Collin, S. P., 1989; Wong, R. O. L., 1990) and DS responses in ganglion cells can be recorded at eye opening (Masland, R. H., 1977). SACs, which appear very early during development (Feller, M. B. *et al.*, 1996), might act as a scaffold for DSGCs as their dendrites are often surrounded by the dendrites of DSGCs in a fascicle (Vaney, D. I. and Pow, D. V., 2000; Stacy, R. C. and Wong, R. O. L., 2003). In the developing retina, the SAC network is dominated by excitatory cholinergic interactions and involved in generating activity waves (reviewed in Masland, R. H., 2005), which may participate in the generation of the DS circuitry.

1.19.5 The Role of Direction-Selective Signals Originating in the Retina

Considering the effort the retina puts into DS computation, it is surprising that the direction-selective neurons in the visual cortex probably recompute motion direction from nondirectional inputs (reviewed in Clifford, C. W. and Ibbotson, M. R., 2003). This seems to suggest that retinal DSGCs do not substantially contribute to cortical processing of motion and its

direction, but at the present time the exact role that retinal DS plays in higher vision is unknown.

It is known, however, that ablation of SACs, which abolishes retinal DS, results in a complete loss of the optokinetic reflex (Yoshida, K. *et al*., 2001; Amthor, F. R. *et al*., 2002), showing that DSGCs provide signals essential for the control of eye movement and gaze stabilization (reviewed in Vaney, D. I. *et al*., 2001). This is possibly the main task of ON DSGCs (Oyster, C. W. *et al*., 1972), because they prefer global motion, as caused by image slippage, and their preferred directions (Figure 1(b), bottom) correspond to the three axes of the semicircular canals in the inner ear. Moreover, ON DSGCs project to the accessory optic system (AOS) rather than to the superior colliculus (SC) and the lateral geniculate nucleus (LGN) like the majority of other ganglion cell types. ON/OFF DSGCs signal local motion (Wyatt, H. J. and Daw, N. W., 1975). They are attenuated by a synchronously moving background; thus, they are sensitive to motion contrast (Chiao, C. C. and Masland, R. H., 2003). The ON/OFF DSGCs' four preferred directions (Figure 1(b), bottom) are roughly aligned with the direction of apparent movement caused by contraction of the eye's rectus muscles (Oyster, C. W. and Barlow, H. B., 1967). The cells provide some input to the AOS and therefore contribute to the optokinetic system, likely for higher velocities. In addition, ON/OFF DSGCs send collaterals to the SC and the LGN and, therefore, may serve other visual functions, such as directing spatial attention to moving objects.

Glossary

circadian rhythm An endogenously generated biological rhythm with a period of about 24 h.

melanopsin The opsin-based photopigment of intrinsically photosensitive retinal ganglion cells.

nonvisual photophysiology Physiological responses to light that do not require the formation of images.

photoentrainment The synchronization of circadian rhythms to the daily light–dark cycle.

1.20.1 Discovery of Melanopsin

The discovery of the photopigment melanopsin has led to the identification of intrinsically photosensitive retinal ganglion cells (ipRGCs), a novel class of photoreceptor in the mammalian retina. This unique cell type plays a role in controlling many forms of light-regulated physiology that do not require the formation of images. Examples of such physiology include the synchronization of circadian rhythms to the day–night cycle (entrainment), the acute photoregulation of pineal melatonin synthesis, and the pupillary light reflex (PLR). Evidence is emerging that these melanopsin-based photoreceptors may also play a role in the regulation of the visual system proper (Dacey, D. M. *et al.*, 2005; Barnard, A. R. *et al.*, 2006).

Melanopsin was initially cloned from cultured dermal melanophores of *Xenopus laevis*. Melanophores are inherently photosensitive (Provencio, I. *et al.*, 1998). In the dark, melanosomes remain aggregated in a perinuclear domain giving the cells a blanched appearance. Upon illumination, the cells darken by distributing the melanosomes throughout the cytoplasm. This response is retinoid dependent suggesting the involvement of an opsin-based photopigment (Rollag, M. D., 1996). In an effort to identify such a photopigment, a *Xenopus* melanophore cDNA library was screened with a cocktail of probes derived from *Xenopus* rhodopsin and violet opsin nucleotide sequences (Provencio, I. *et al.*, 1998). This screen yielded a partial clone with a predicted amino acid sequence more similar to the opsins contained in rhabdomeric photoreceptors of invertebrates than the opsins of ciliary photoreceptors of vertebrates. A full-length clone was obtained and subsequently named melanopsin because of its derivation from melanophores. Expression of melanopsin transcripts in melanophores was verified by *in situ* hybridization studies (Provencio, I. *et al.*, 1998). These studies also demonstrated expression in several brain regions, iridial myocytes, and the retina. The retinal expression pattern was peculiar because it was restricted to the ganglion cell and inner nuclear layers which contain cells not previously believed to be photosensitive. This finding suggested that nonrod, noncone photoreceptors may be lurking in the vertebrate retina.

1.20.2 Identification of Mammalian Melanopsin Homologs

Using the nucleotide sequence information derived from amphibians, a chicken melanopsin homolog was identified (Chaurasia, S. S. *et al.*, 2005). Mammalian homologs were subsequently cloned from mice and humans using the chicken-derived sequence (Provencio, I. *et al.*, 2000). Both mammalian and non-mammalian versions share the molecular hallmarks common to all opsins such as a lysine residue in the predicted seventh transmembrane domain that is necessary for the covalent Schiff base linkage of the retinoid chromophore. As previously mentioned, melanopsins share greater amino acid similarity with rhabdomeric photoreceptor opsins than the visual opsins of vertebrates. Despite this invertebrate-like character, melanopsin homologs have not been found in true invertebrates, although, a melanopsin homolog has been identified in a cephalochordate (Koyanagi, M. *et al.*, 2005). In addition to the general similarity to rhabdomeric opsins, melanopsins also share individual molecular traits specific to rhabdomeric opsins. Most obvious among these is the aromatic residue in the third transmembrane domain (Provencio, I. *et al.*, 1998; 2000), a site in vertebrate rod and cone opsins that is occupied by an acidic residue which is necessary for salt-bridge formation with the protonated Schiff base (Kim, J. M. *et al.*, 2005).

In nonmammalian vertebrates, melanopsin is expressed in multiple tissues believed to be intrinsically photosensitive such as the pineal gland and areas of the deep brain (Provencio, I. *et al.*, 1998; Bellingham, J. *et al.*, 2002; Drivenes, O. *et al.*, 2003; Bailey, M. J. and Cassone, V. M., 2005; Chaurasia, S. S. *et al.*, 2005; Tomonari, S. *et al.*, 2005; Bellingham, J. *et al.*, 2006; Frigato, E. *et al.*, 2006). By contrast, the expression pattern in mammals is extremely restricted. In rodents, melanopsin expression is confined to 1–2% of retinal ganglion cells (RGCs; Hattar, S. *et al.*, 2002; Morin, L. P. *et al.*, 2003; Sollars, P. J. *et al.*, 2003; Hattar, S. *et al.*, 2006). Reverse transcriptase polymerase chain reaction (RT-PCR) of 26 human tissues revealed that melanopsin expression was limited to the retina (Provencio, I. *et al.*, 2000).

A second melanopsin gene has been identified in nonmammalian vertebrates (Bellingham, J. *et al.*, 2006). Based on synteny between the chicken and human genomes, it is clear that this second gene has been lost in mammals. Both genes appear capable of coding functional opsin proteins, however, the consequences of possessing two melanopsin genes remains to be determined.

1.20.3 Identification of Intrinsically Photosensitive Retinal Ganglion Cells

In the absence of rods and cones, visually blind mice homozygous for the *retinal degeneration* (*rd*) allele continue to photoregulate circadian locomotor rhythms in a manner indistinguishable from sighted controls (Foster, R. G. *et al.*, 1991). The spectral sensitivity for this response to light peaks in the blue wavelengths (480 nm; Yoshimura, T. and Ebihara, S., 1996; Hattar, S. *et al.*, 2003). The PLR in rodless, coneless (*rd*/*rd cl*) mice is also maximally sensitive to blue light (479 nm; Lucas, R. J. *et al.*, 2001). In humans, elevated nocturnal serum melatonin can be suppressed acutely by a pulse of light. Again, the spectral sensitivity of this response is maximal in the blue wavelengths (446–477 nm), a spectral domain not consistent with the well-characterized sensitivities of human rod and cone photoreceptors (Brainard, G. C. *et al.*, 2001; Thapan, K. *et al.*, 2001). Together, these findings suggested the existence of a nonrod, noncone class of photoreceptor that mediates these distinctly different nonvisual responses to light. Localization of melanopsin to a small set of RGCs pointed to a potentially novel photoreceptor class; the presence of a putative photopigment in RGCs implied that these cells are inherently photoreceptive. Berson D. M. *et al.* (2002) painstakingly proved this seemingly heretical implication to be the case.

The vast majority of melanopsin-containing RGCs project to the hypothalamic suprachiasmatic nuclei (SCN), a retinorecipient site and master circadian oscillator (Gooley, J. J. *et al.*, 2001; Hannibal, J. *et al.*, 2002a; Gooley, J. J. *et al.*, 2003; Morin, L. P. *et al.*, 2003; Sollars, P. J. *et al.*, 2003). Berson D. M. *et al.* (2002) retrogradely labeled SCN-projecting RGCs and recorded light-evoked membrane depolarizations from these cells even when they were pharmacologically deafferented; synaptic blockers were used to prevent signaling to those cells through rod or cone pathways. The intrinsic photosensitivity of these cells was shown unequivocally by the persistence of such light responses in labeled cells physically teased away from the RGC layer (Berson, D. M. *et al.*, 2002). Later studies confirmed that melanopsin does indeed confer photosensitivity upon ipRGCs (Lucas, R. J. *et al.*, 2003; Tu, D. C. *et al.*, 2005). Interestingly, like the action

spectra of circadian photoregulation and melatonin photosuppression, light responses in ipRGCs peak in the blue wavelengths (479 nm), thereby implicating this new class of melanopsin-based ganglion cell photoreceptor in the regulation of these nonvisual responses (Berson, D. M. *et al.*, 2002).

Unlike rods and cones that hyperpolarize in response to light, ipRGCs depolarize upon photic stimulation. Heterogeneity exists in these responses. The use of multielectroarrays (MEA) has facilitated the simultaneous recording from multiple ipRGCs (Tu, D. C. *et al.*, 2005). Using this tool, at least three electrophysiological phenotypes can be discriminated in neonates. Only two of these remain in adult mice (Table 1). No obvious distinguishing morphological characteristics correlate with these physiological phenotypes.

The onset of melanopsin expression occurs early in prenatal development in chickens, mice, and humans (Tarttelin, E. E. *et al.*, 2003; Tomonari, S. *et al.*, 2005). In mice, the number of ipRGCs at birth is at least fivefold greater than in the adult (Sekaran, S. *et al.*, 2005). There is also a general increase in sensitivity as ipRGCs mature. While ipRGCs can respond to light at birth (Hannibal, J. and Fahrenkrug, J., 2004), the responses are relatively insensitive and transient (Sekaran, S. *et al.*, 2005). Responses after the sixth postnatal day are around tenfold more sensitive and can persist after stimulus offset. Taken together, it has been unequivocally established that ipRGCs are the first light-sensitive cells to develop in the retina.

Adaptation, the dynamic regulation of sensitivity, is a hallmark of rods and cones that makes vision possible in light levels ranging from dim starlight to bright sunlight (Rodieck, R. W., 1998). The photic responses of ipRGCs and the behavioral outputs to which they contribute, such as pupillary constriction, are sustained in nature, suggesting that perhaps ipRGCs do not adapt. To the contrary, ipRGCs are capable of dark- and light-adaptation in response to lighting history (Wong, K. Y. *et al.*, 2005). Furthermore, adaptation occurs in the presence of pharmacologic synaptic blockers indicating that such an adjustment of sensitivity is an intrinsic property of ipRGCs and does not emerge from a network of communicating cells.

Table 1 Physiological phenotypes of intrinsically photosensitive retinal ganglion cells (ipRGCs; derived from Tu, D. C. *et al.*, 2005)

Type	*Sensitivity*[a]	*Termination*[b]
Type I[c]	$\sim 10^{12}$	~10 s
Type II	$>10^{13}$	~30 s
Type III	$\sim 10^{12}$	From 30 s to 2 min

[a] Half maximal response in photons s^{-1} cm^{-2} of 480 nm light.
[b] Amount of time after end of stimulus at which firing rate returns to baseline.
[c] Only observed in neonates (postnatal day 8).

The density of melanopsin RGCs is constant across the retinas of hamsters (Morin, L. P. *et al.*, 2003; Sollars, P. J. *et al.*, 2003) and mice (Lin, B. *et al.*, 2004), but rats and primates show a shallow density cline peaking in the superiotemporal (Hannibal, J. *et al.*, 2002a; Hattar, S. *et al.*, 2002) and parafoveal (Dacey, D. M. *et al.*, 2005) retinal domains, respectively. Electron microscopy confirms that melanopsin, like all opsin-based photopigments, is an integral membrane protein (Belenky, M. A. *et al.*, 2003). It is localized to the plasma membrane of the perikaryal, dendritic, and axonal domains of ipRGCs (Beaule, C. *et al.*, 2003; Provencio, I. *et al.*, 2002). Antimelanopsin immunoreactivity has been observed even in axon terminals within the SCN (Beaule, C. *et al.*, 2003). Dendritic immunoreactivity is spatially coincident with the receptive fields of ipRGCs, indicating the presence of functional photopigment out to the distal tips of dendrites (Berson, D. M. *et al.*, 2002).

Murine ipRGCs have relatively small cell bodies (~20 µm) that elaborate 2 or 3 primary dendrites which initially bifurcate within 50 µm of the cell body (Lin, B. *et al.*, 2004). Some somata are displaced into the inner aspect of the inner nuclear layer (Provencio, I. *et al.*, 2000; Hattar, S. *et al.*, 2002). Dendritic arbors are relatively sparse, having mean diameters of around 450 µm in mice (Lin, B. *et al.*, 2004) and 600 µm in rats (Warren, E. J. *et al.*, 2003), and are regularly tiled across the retina with substantial overlap (Lin, B. *et al.*, 2004). Pituitary adenylyl cyclase-activating peptide (PACAP) and glutamate are colocalized with melanopsin in ipRGCs (Hannibal, J. *et al.*, 2000; 2002a; 2004). The morphology of these cells is quite distinctive. Most striking are the regularly spaced varicosities that decorate the arbor, giving a rosary beads appearance (Hannibal, J. *et al.*, 2002a; Hattar, S. *et al.*, 2002; Provencio, I. *et al.*, 2002; Belenky, M. A. *et al.*, 2003; Panda, S. *et al.*, 2003; Sollars, P. J. *et al.*, 2003; Lin, B. *et al.*, 2004). The dendrites ramify into sublaminas S1 and S5 of the inner nuclear layer (Provencio, I. *et al.*, 2002; Belenky, M. A. *et al.*, 2003; Dacey, D. M. *et al.*, 2005). Whether each of these plexuses arises from a distinct subclass of ipRGCs or whether a single class is bistratified remains to be determined (Hattar, S. *et al.*, 2006; Figure 1).

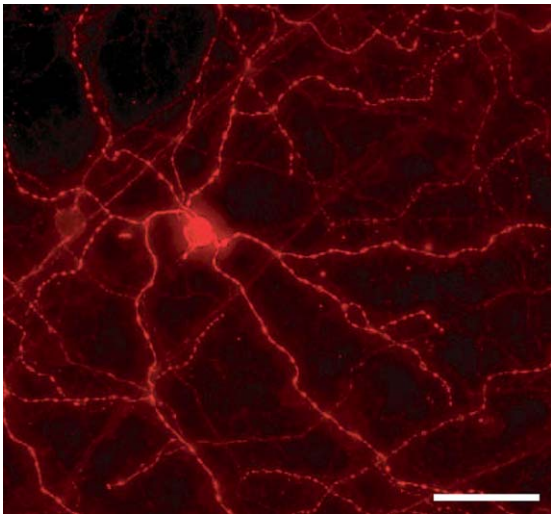

Figure 1 Scanning confocal photomicrograph of melanopsin immunopositive retinal ganglion cell seen in a flat-mounted mouse retina. Scale bar = 25 μm. Reproduced from Belenky, M. A., Smeraski, C. A., Provencio, I., Sollars, P. J., and Pickard, G. E. 2003. Melanopsin retinal ganglion cells receive bipolar and amacrine cell synapses. J. Comp. Neurol. 460, 380–393, with permission from John Wiley & Sons, Inc.

The principle central targets of ipRGCs are the SCN, the intergeniculate leaflet, the lateral habenula, and the olivary pretectal nucleus (Gooley, J. J. *et al.*, 2001; Hattar, S. *et al.*, 2002; Hattar, S. *et al.*, 2006; Figure 2). The secondary central targets are the subparaventricular zone, perisupraoptic nucleus, ventrolateral preoptic nucleus, ventral lateral geniculate nucleus, and superior colliculus (Gooley, J. J. *et al.*, 2003; Hattar, S. *et al.*, 2006). Also of note is the relative absence of ipRGC terminals in the rodent dorsal lateral geniculate nucleus (dLGN), a retinotopically mapped thalamic relay important in the construction of images (Hattar, S. *et al.*, 2006). This is in contrast to the primate brain where ipRGCs project to the dLGN (Dacey, D. M. *et al.*, 2005).

1.20.4 Functional Characterization of Intrinsically Photosensitive Retinal Ganglion Cells

The similarity between the spectral responses of ipRGCs (Berson, D. M. *et al.*, 2002) and the previously mentioned wavelength sensitivities of nonvisual responses to light (Yoshimura, T. and Ebihara, S., 1996; Brainard, G. C. *et al.*, 2001; Lucas, R. J. *et al.*, 2001; Thapan, K. *et al.*, 2001; Hattar, S. *et al.*, 2003) provides insight into the potential roles of this novel class of photoreceptor. In addition, many of the functions of the retinorecipient targets of ipRGCs have been well studied, thereby offering indirect clues to other potential functions of ipRGCs (Gooley, J. J. *et al.*, 2003; Morin, L. P. *et al.*, 2003; Hattar, S. *et al.*, 2006; Morin, L. P. and Allen, C. N., 2006). To directly establish the function of ipRGCs, three lines of melanopsin-null ($Opn4^{-/-}$) mice were independently generated (Hattar, S. *et al.*, 2002;

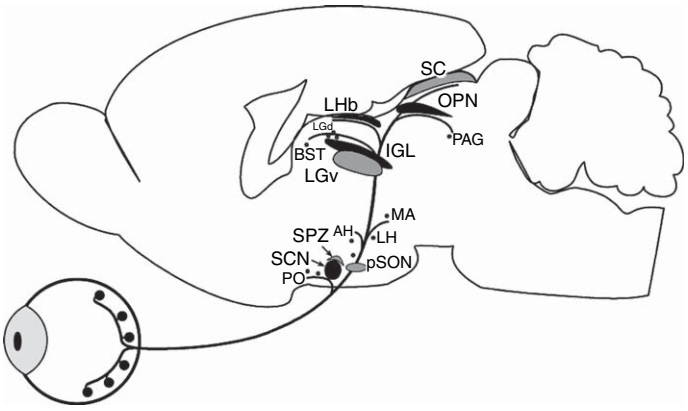

Figure 2 Central projections of intrinsically photosensitive retinal ganglion cells (ipRGCs). Principle targets are indicated in dark gray and secondary targets in light gray. Minor targets are indicated by dots. AH, anterior hypothalamic nucleus; BST, bed nucleus of the stria terminalis; IGL, intergeniculate leaflet; LGd, lateral geniculate nucleus, dorsal division; LGv, lateral geniculate nucleus, ventral division; LH, lateral hypothalamus; LHb, lateral habenula; MA, medial amygdaloid nucleus; OPN, olivary pretectal nucleus; PAG, periaqueductal gray; PO, preoptic area; pSON, perisupraoptic nucleus; SC, superior colliculus; SCN, suprachiasmatic nucleus; SPZ, subparaventricular zone. Reproduced from Hattar, S., Kumar, M., Park, A., Tong, P., Tung, J., Yau, K. W., and Berson, D. M. 2006 Central projections of melanopsin-expressing retinal ganglion cells in the mouse. J. Comp. Neurol. 497, 326–349, with permission from John Wiley & Sons, Inc.

Panda, S. *et al.*, 2002; Ruby, N. F. *et al.*, 2002). Surprisingly, all three mouse lines demonstrate that the loss of melanopsin does not cause profound deficits in circadian photoreception or other forms of nonvisual light detection. Under standard 12 h:12 h light–dark lighting conditions, these mice entrain their activity to the light–dark cycle just like wild-type littermates (Panda, S. *et al.*, 2002; Ruby, N. F. *et al.*, 2002). When housed in constant dark, and thereby isolated from temporal cues, $Opn4^{-/-}$ mice express rhythmic locomotor rhythms with circadian periods indistinguishable from $Opn4^{+/+}$ controls (Panda, S. *et al.*, 2002; Ruby, N. F. *et al.*, 2002). Only more sophisticated analyses, such as the circadian phase shifting effect to single pulses of light, reveal that these knockout mice exhibit some deficits. For example, at all irradiances tested, $Opn4^{-/-}$ mice show smaller light-induced phase shifts than melanopsin-intact mice. Additionally, the degree of circadian period lengthening observed in melanopsin-null mice maintained in constant light also was significantly blunted (Panda, S. *et al.*, 2002; Ruby, N. F. *et al.*, 2002). Like the regulation of circadian behavior, the PLR also is affected in significant but subtle ways. At nonsaturating irradiances, $Opn4^{-/-}$ mice do not differ from wild-type mice, however, at saturating irradiances, $Opn4^{-/-}$ mice fail to constrict the pupil fully (Hattar, S. *et al.*, 2003; Lucas, R. J. *et al.*, 2003; Panda, S. *et al.*, 2003).

The presence of residual responses in these animals suggests that rods and cones may, in the end, contribute to nonimage-forming photoreception. To address this possibility, melanopsin-null mice have been crossed with mice possessing functionally deficient rods and cones or missing the visual photoreceptors altogether (Hattar, S. *et al.*, 2003; Panda, S. *et al.*, 2003. The lack of functional rods, cones, and ipRGCs renders these animals visually and nonvisually blind; they behave as though they have been bilaterally enucleated. Unlike *rd* mice or mice only null for melanopsin, no responses to light could be recorded in these triple-knockout animals. Among the responses assessed were circadian photoentrainment, light-induced circadian phase shifting, acute light-evoked suppression of nocturnal activity (masking), constant-light circadian period lengthening, light-mediated suppression of the melatonin biosynthesis pathway, and the PLR (Hattar, S. *et al.*, 2003; Panda, S. *et al.*, 2003). Taken together, these data demonstrate the involvement of rods, cones, and ipRGCs in nonvisual photophysiology. The relative contributions of these photoreceptor classes to nonvisual light responses remains to be determined. The use of classical knockout strategies may not prove fruitful to this end. The impact of compensation elicited by the early developmental loss of melanopsin is difficult to quantify. Inducible knockout models should prove more useful in establishing the relative roles of rods, cones, and ipRGCs in nonvisual photoreception.

Melanopsin's role as a photopigment of nonvisual photoreceptors is perhaps best demonstrated by its presence in an obligate irradiance detector (Hannibal, J. *et al.*, 2002b). The eye of the blind mole rat (*Spalax* sp.) is atrophied and subcutaneous, thereby incapable of form vision (Cooper, H. M. *et al.*, 1993). Furthermore, anatomical and electrophysiological assessment of central visual structures also indicates an absence of a functional visual system. Like retinally degenerate mouse models, *Spalax* can entrain to daily light–dark cycles (Tobler, I. *et al.*, 1998; Avivi, A. *et al.*, 2001). The retina of Spalax only contains about 900 RGCs, but many of these cells contain melanopsin (Hannibal, J. *et al.*, 2002b). A long wavelength-sensitive (LWS) cone photopigment also has been cloned from *Spalax* retina (David-Gray, Z. K. *et al.*, 1999). The relative contributions to photoentrainment of the photoreceptive cells that harbor the LWS cone photopigment and the RGCs that express melanopsin remain to be determined.

1.20.5 Role of Intrinsically Photosensitive Retinal Ganglion Cells in Vision

Although little evidence exists suggesting that ipRGCs are involved in rodent vision, the situation in primates is quite different (Dacey, D. M. *et al.*, 2005). Melanopsin is expressed in giant RGCs which project to the lateral geniculate nucleus. The dendritic arbor diameters of these cells approach 1 mm and are the largest of the identified primate RGC classes. Only 3000 giant cells exist in the primate retina representing 0.2% of all RGCs. These cells are intrinsically photoreceptive, displaying a peak spectral sensitivity in the blue wavelengths (482 nm). Giant RGCs also are activated by rods and cones. Activation by cone pathways exhibit (L + M)-cone On S-cone Off chromatic opponency. Although relatively insensitive compared to rods and cones, the intrinsic photosensitivity of giant RGCs is highly correlated with the intensity of the stimulus,

thereby indicating precise irradiance coding. At irradiances subthreshold to the intrinsic sensitivity, giant cells receive irradiance-dependent information from rods and cones. Therefore, giant cells are capable of integrating and transmitting irradiance information across the entire dynamic range (scotopic, mesopic, and photopic) of the visual system (Dacey, D. M. *et al.*, 2005).

1.20.6 Melanopsin-Activated Phototransduction

The greater similarity of melanopsin to opsins of invertebrates than those of vertebrates has suggested that melanopsin may signal through a rhabdomeric-like phototransduction cascade through a $G\alpha_q/G\alpha_{11}$ G protein pathway (Arendt, D., 2003; Isoldi, M. C. *et al.*, 2005). Overexpression of melanopsin in amphibian dermal melanophores hypersensitizes them to light, indicating a prominent role for melanopsin in phototransduction (Rollag, M. D. *et al.*, 2000). As previously mentioned, *Xenopus* melanophores respond to light by dispersing their melanin granules, thereby increasing their optical density. This provides the experimentalist an easily quantifiable output. Melanophores can be cultured in the presence or absence of signaling inhibitors and these effects can be measured with a standard plate reader to gain insight into the potential signaling pathways involved (Rollag, M. D. *et al.*, 2000).

Melanosome dispersion in response to α-melanocyte-stimulating hormone is a well-studied cyclic AMP (cAMP)-dependent process (Nery, L. E. and Castrucci, A. M., 1997). However, light exposure does not increase intracellular cAMP in melanophores and inhibitors of adenylyl cyclase and protein kinase A have no effect on light-induced melanosome dispersion (Isoldi, M. C. *et al.*, 2005). Likewise, inhibitors of guanylyl cyclase and protein kinase G fail to have any effect on the melanophore light response. By contrast, inositol trisphosphate is elevated in response to light and inhibitors of phospholipase C (PLC) and protein kinase C (PKC) dramatically inhibit melanosome photodispersion. Furthermore, chelating intracellular calcium blocks the light response. These data, in concert with the observation that light causes a PKC-dependent phosphorylation of melanophore proteins indicate that melanopsin signals through a phosphoinositide pathway similar to the rhabdomeric photoreceptors of invertebrates (Isoldi, M. C. *et al.*, 2005). As previously mentioned, a second melanopsin gene has been discovered in nonmammalian vertebrates which seems to have been lost in mammals (Bellingham, J. *et al.*, 2006). Although, no opsins other than melanopsin are expressed in the melanophore cell line (Isoldi, M. C. *et al.*, 2005), it is unclear if one or both melanopsins are involved in initiating a phosphoinositide signaling cascade.

Melanopsin-initiated phototransduction, has also been studied by expressing the photopigment in cell lines (Koyanagi, M. *et al.*, 2005; Melyan, Z. *et al.*, 2005; Qiu, X. *et al.*, 2005). These heterologous systems provide many advantages for the study of photopigments, such as melanopsin, that have a very restricted tissue distribution. Primary among these benefits is the generation of many photopigment-expressing cells, providing sufficient material for biochemical studies. Typically, the cell lines used for heterologous expression are not inherently light-sensitive, thereby providing confidence that any light-evoked responses are attributable to the transfected photopigment. Melanopsin has been transiently expressed in several cell lines (Koyanagi, M. *et al.*, 2005; Melyan, Z. *et al.*, 2005; Qiu, X. *et al.*, 2005) and *Xenopus* oocytes (Panda, S. *et al.*, 2005). Some of these studies have shown that photoactivation of melanopsin promotes an intracellular increase in calcium (Melyan, Z. *et al.*, 2005; Qiu, X. *et al.*, 2005). Furthermore, studies using a human embryonic kidney cell line (HEK293-TRPC3) demonstrate that this rise in calcium is triggered by a phosphoinositide signaling cascade as in melanophores (Kumbalasiri, T. and Provencio, I., 2005). The basis of the photo-induced increase in intracellular calcium in melanopsin-transfected Neuro2A cells remains to be determined (Melyan, Z. *et al.*, 2005).

Heterologous expression of melanopsin has proven to be a useful approach to gain insight into the potential pathways of transduction. However, such a pharmacologic dissection has not been extended to mammalian ipRGCs. Experiments on the avian retina have been more productive. Contin M. A. *et al.* (2006) have shown that the light-induced suppression of melatonin production in chicken RGC cultures can be blocked through the use of inhibitors of phosphoinositide signaling or chelation of intracellular calcium. This study represents the first demonstration of a phosphoinositide phototransduction cascade in a vertebrate retina.

Melanopsin-initiated signaling through a $G\alpha_q/G\alpha_{11}$ pathway comports with melanopsin's rhabdomeric character (Arendt, D., 2003). Bistability is another characteristic of rhabdomeric opsin-based signaling. For example, *Drosophila* rhodopsins exhibit

a thermostable metastate and are capable of autonomously photoregenerating in the absence of a retinoid cycle (Hardie, R. C. and Raghu, P., 2001). Expression of amphioxus melanopsin in HEK293S cells has revealed a bistable spectral absorbance similar to squid rhodopsin; at neutral pH, irradiation with blue light generates a red-shifted photoproduct which can be reverted to the original spectral state by irradiation with orange light (Koyanagi, M. *et al.*, 2005). Other studies have also suggested a bistable nature of melanopsin (Fu, Y. *et al.*, 2005; Melyan, Z. *et al.*, 2005; Panda, S. *et al.*, 2005). Such a self-sufficient chromophore-handling strategy would be highly adaptive for photoreceptive cells not anatomically juxtaposed to a retinoid cycling tissue such as the retinal pigment epithelium.

1.20.7 Conclusion

The eye has been extensively studied for over a century. The relatively recent discovery of melanopsin-containing ipRGCs represents a novel photosensory system in the retina that has been literally overlooked. All future studies in retinal physiology must consider the potential contributions of this system.

Glossary

tritan, tritanopia Tritanopia refers to the form of color blindness associated with absence of the short-wavelength cones. Such individuals are unable to distinguish colors that lie along a tritanopic confusion line in color space (along which only short-wavelength cone excitation varies). Individuals with normal color vision rely on short-wavelength cones to distinguish such colors. Stimuli that modulate along a tritan line are often used, psychophysically and physiologically, to isolate short-wavelength cone (colloquially blue–yellow) mechanisms.

1.21.1 Introduction

A cone with peak absorption in the short-wavelength region of the visible spectrum (400–500 nm), commonly termed the short-wavelenth (s) cone is common to most mammalian species (Jacobs, G. H., 1993) and presumably some form of blue–yellow color vision is present among them. However, there are only sparse reports on the physiology of these pathways in nonprimates. For example, cells with S-cone input have been reported in the cat retina (Cleland, B. G. and Levick, W. R., 1974) but little quantitative detail is available about their properties, or on blue–yellow discrimination ability in this (or other) species. Since blue–yellow color vision is thought to be phylogenetically ancient (Mollon, J. D., 1989), it is tempting to assume that blue-ON cell ganglion cell anatomy and physiology is similar in all mammals with S cones, but there is little or no evidence for this supposition.

Primates are the only mammals to possess full trichromatic vision, with middle-wavelength (M) and long-wavelength (L) cones as well as the S cone. The characteristics of the red–green color opponent pathway are discussed elsewhere in this volume. The blue–yellow opponent pathway forms a separate system, beginning in at least two ganglion cell classes, passing through the koniocellular layers of the lateral geniculate nucleus (LGN) to striate cortex. The best-studied of the ganglion cell classes is the small bistratified cell, which forms the main focus of this article. A more extensive overview of the S cones and their ganglion cell classes has been provided by Calkins D. J. (2001), and a complementary overview can be found in Dacey D. M. and Packer O. S. (2003).

1.21.2 Early Studies

Recordings from retinal ganglion cells and LGN neurons of the macaque (DeValois, R. L., 1971; Gouras, P. and Zrenner, E., 1981) revealed cells excited by lights of short wavelength and inhibited by lights through the rest of the spectrum. This would imply cells with excitatory input from S cones and inhibitory inputs from the other cone types. Such cells are colloquially known as blue-ON cells, and it has turned out that three other cell types have S-cone input, as described in a later section.

How far do these ganglion cells exclusively carry S-cone signals? Experiments using differential adaptation suggested that small S-cone inputs might be present to, for example, some red–green opponent cells (de Monasterio, F. M. *et al.*, 1975). However, it was unclear whether such an input, if present, played a significant role in cell responses under more neutral adaptation conditions. More sophisticated stimulus techniques, in which cell responses were measured to modulation around a neutral mean chromaticity, showed that S-cone inputs were not readily detected to ganglion classes other than those with major S-cone input (Derrington, A. M. *et al.*, 1984; Lee, B. B. *et al.*, 1987). These early measurements might not have detected weak inputs, but recently experiments using a more sensitive means for detecting S-cone input have shown that input to red–green opponent and parasol or magnocellular cells is very small indeed (Sun, H. *et al.*, 2006b), and that these cells must avoid S-cone input (Sun, H. *et al.*, 2006a). Thus, the blue-ON cell and a few other cell types carry exclusive responsibility for transmitting S-cone signals to the brain.

1.21.3 Anatomical Substrate

The small bistratified ganglion cell was described by Rodieck R. W. (1991) and Dacey D. M. (1993) provided strong anatomical evidence that it corresponded to the blue-ON cell. One inner dendritic layer ramifies close to the cell body, in the most vitreal stratum of the inner plexiform layer (IPL) near where the S-cone bipolar terminates (Kouyama, N. and Marshak, D. W., 1992). The outer layer of its dendrites ramifies in the outermost stratum of the IPL, is less dense and slightly smaller in diameter. A sketch of this arrangement in shown in Figure 1. The blue-ON circuitry is sketched, and the inner and outer dendritic trees of a small bistratified cell are shown. Overall dendritic tree size is slightly larger than parasol cells at the same eccentricity (Dacey, D. M., 1993). The small bistratified cell forms a single mosaic across the retina, suggesting a functionally homogenous cell class. One other feature is that there is electrotonic coupling to a small-field amacrine cell class. Physiological recordings from cells that were then stained with neurobiotin confirmed that these cells were members of the blue-ON class (Dacey, D. M. and Lee, B. B., 1994). One hypothesis as to the physiological basis of blue–yellow opponency is that excitatory S-cone input is received in the inner dendritic layer via the S-cone bipolar, and inhibitory input is received into the outer dendrites through some unidentified off diffuse bipolar. However, the basis of the opponency is likely to be more complicated. After blocking of the on pathways pharmacologically, not only is the blue-ON signal lost, but also most of the inhibitory response from the M and L cones (Dacey, D. M., 2000). It may be that some degree of blue–yellow opponency is already present in the blue-ON bipolar cell. In outer retina, the HII horizontal makes contact with both the S cones and the M and L cones (Dacey, D. M. *et al.*, 1996); all cone types hyperpolarize the cell. An opponent M,L-cone input could derive from horizontal cells to the S-cone bipolar and thence to the ganglion cell. Alternatively, the electrotonically coupled amacrine cell class may play a role. The relative weights of these contributions remain to be determined.

Since the proportion of S cones in the mosaic is small, the S-cone receptive field of the small bistratified cell must be nonuniform, in that only a few S cones can provide input. In elegant measurements using a multielectrode array so that local mapping of the inputs from S cones could be achieved, Chichilnisky E. J. and Baylor D. A. (1999) showed that small bistratified cells received major input from just one or two S cones, and that these inputs summed linearly. The punctate distribution of S cones must affect the response of such cells to spatial patterns; for example, drifting tritan gratings (just modulating the S cone) with a period length close to the field width would alias with the S-cone inputs. In any event, the results of Chichilnisky and Baylor form a basis for the psychophysical detectability of the S-cone mosaic (Williams, D. R. *et al.*, 1981).

The small bistratified cell was originally identified following injections of horseradish peroxidase in the parvocellular (PC) layers of the LGN (Watanabe, M. and Rodieck, R. W., 1989), and was assumed to be part of this afferent system. However, it is now clear that the intercalated, koniocellular layers of the LGN represent a separate system, and most if not all cells with S-cone input project to the cortex through this pathway (White, A. J. R. *et al.*, 1998; Szmajda, B. A. *et al.*, 2007). The earlier injections were not specific enough to make this distinction. This is consistent with the view that this pathway existed in mammals before the primate PC and magnocellular (MC) afferent pathways emerged. It now appears that this opponent color system terminates in a superficial layer of the cortex (Chatterjee, S. and Callaway, E. M., 2003), separately from the other systems.

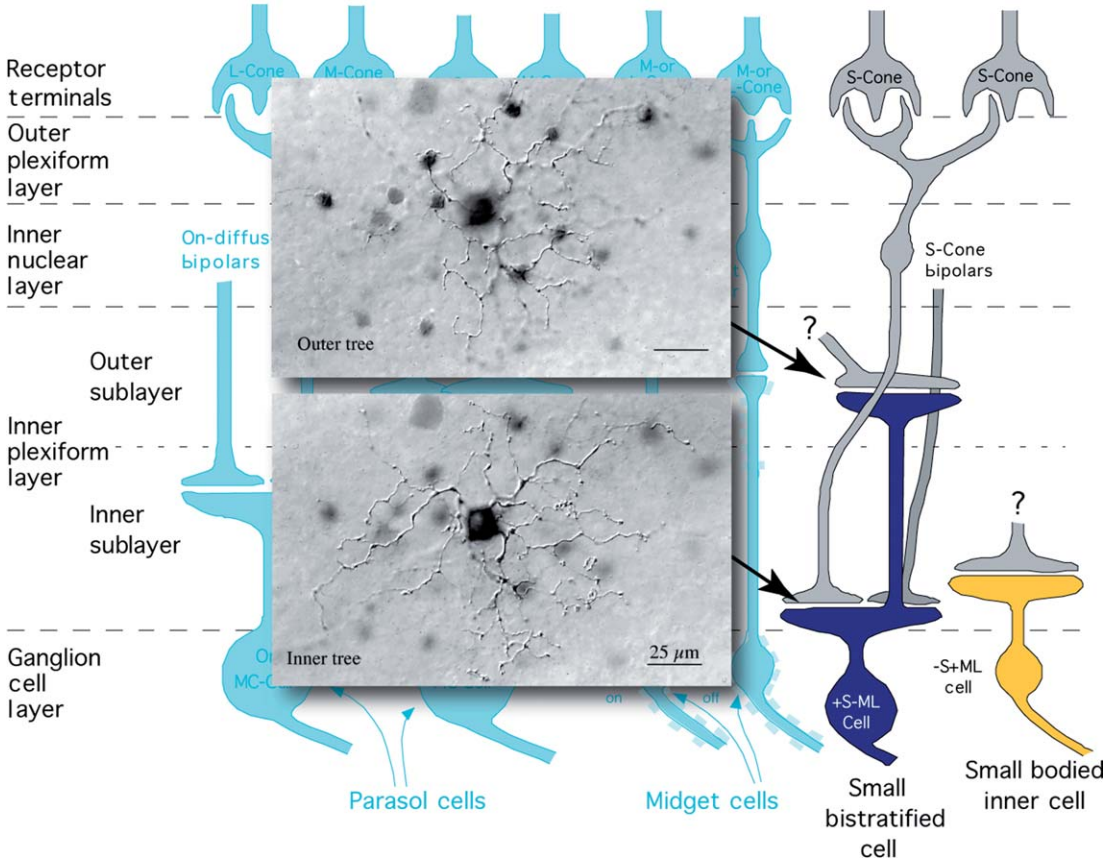

Figure 1 A sketch of blue-ON circuitry. The small bistratified cell has two layers of dendrites stratifying in the inner and outer strata of the inner plexiform layer. The micrographs show typical dendritic trees of the two strata, following neurobiotin staining after recording, viewed with different levels of focus in the retinal wholemount. In each, one layer of dendrites can be seen to be in focus, and the other blurred. The outer tree is sparser and smaller than the inner tree. The input to the inner tree is from the small-wavelength (S)-cone bipolar, the input to the outer tree is uncertain. There is also sketched the small field ganglion cell believed to correspond to the blue-OFF cell.

1.21.4 Current Views of Cell Physiology

It is well established that the blue-ON cell receives excitatory input from the S-cone and inhibitory input from the other two cone types. The L/M weighting of this inhibitory input may be random. One study specifically assessed this issue and found input from both L and M cones but with considerable variability (Smith, V. C. *et al.*, 1992), and other studies have also suggested combined input (Lee, B. B. *et al.*, 1987; Chichilnisky, E. J. and Baylor, D. A., 1999). As far as receptive field structure is concerned, the spatial extent of the antagonistic mechanisms is roughly coextensive (Solomon, S. G. *et al.*, 2005), as might be expected if the two layers of dendrites determined the extent of the opponent mechanisms. However, as noted above, the source of the M,L cone signal is still unsure.

Early studies of blue-ON cells found that their responses could be adequately described by linear combination of cone inputs (Derrington, A. M. *et al.*, 1984; Lee, B. B. *et al.*, 1987). Consistent with the linear model, the blue-ON cell underlies detection of S stimuli superimposed upon an achromatic background (Crook, J. M. *et al.*, 1987). However, psychophysical results associated with the S-cone system suggest some nonlinear features. In particular, immediately after exposure to strong yellow or blue adapting fields, sensitivity to S-cone increments is depressed; this is termed transient tritanopia (Mollon, J. D. and Polden,

P. G., 1980; Mollon, J. D. *et al.*, 1987), and appears to be due to the blue–yellow opponent system being driven into temporary saturation before it recovers with a time course of several seconds. This phenomenon appears to have a physiological basis at the ganglion cell level (Zrenner, E. and Gouras, P., 1981). It is unclear whether this is because it is easy to drive this color opponent system into saturation, since the S cone is spectrally well separated from the M and L cones, or whether it is because of some inherent nonlinearity of this pathway. The M and L cones are closer together spectrally, and it may be more difficult to provide for the red–green system such strong differential adaptation as can be achieved with the blue–yellow pathway. Physiologically however, midget, PC cells show similar effects (Yeh, T. *et al.*, 1996), although they have been difficult to detect psychophysically (Reeves, A., 1981). Van Hateren J. H. *et al.* (2002), when modeling blue-ON cell responses to natural scenes, found evidence for some kind of long-term adaptation effects, which were absent from midget, red–green opponent ganglion cells.

From early psychophysical measurements of S-cone modulation sensitivity it was concluded that this pathway had poor temporal resolution, with the speculation that the S cones themselves might have a sluggish response (Brindley, G. S. *et al.*, 1966). However, the impulse response of individual S cones is of similar duration to the impulse response of M and L cones (Schnapf, J. L. *et al.*, 1990), which would suggest a similar temporal chracteristic. Blue-ON ganglion cells respond up to a frequency of 30–40 Hz with tritan modulation, which is much higher than the frequency at which psychophysical detection of S-cone modulation fails (Yeh, T. *et al.*, 1995). There must therefore be low-pass filtering of the blue-ON cell signal at a central, cortical site, as is the case for PC cells and red–green modulation (Lee, B. B. and Dacey, D. M., 2007).

1.21.5 Other Cells with S-Cone Input

Despite early doubts as to the existence of cells with inhibitory S-cone input, their presence was eventually established in the macaque LGN (Valberg, A. *et al.*, 1986). They receive inhibitory input from the S cone, and some excitatory input from the other cone types, although in one recent study in the marmoset LGN (Szmajda, B. A. *et al.*, 2007) about half the cells in a small sample had no M,L-cone input. It is unclear whether this is a species difference; in the macaque, blue-OFF cells are generally excited by yellow light, and fill in Sloan's notch when chromatic targets are presented on an achromatic background (Crook, J. M. *et al.*, 1987), which suggests excitatory M,L-cone input. In the marmoset study, all cells were found in the koniocellular layers of the LGN, as expected.

The retinal origin of these cells is uncertain. Encounter rates of blue-ONs relative to blue-OFFs tend to be about 3:1 in the LGN (Derrington, A. M. *et al.*, 1984; Valberg, A. *et al.*, 1986; Szmajda, B. A. *et al.*, 2007, #2714), but encounter rates in the retina are lower (Lee, B. B. and Hao Sun, unpublished observations). This may account for early reports that ganglion cells with inhibitory S-cone input were not present (de Monasterio, F. M. and Gouras, P., 1975). Recently, Dacey D. M. and Packer. O. S. (2003) identified a small-field monostratified cell with inhibitory S-cone input (Figure 1), with its dendritic tree branching close to the S-cone-ON bipolar axonal arborization. However, how a sign inversion (how an S-cone-OFF response can be generated from an on signal in the bipolar cell) might be achieved remains unknown. Alternatively, based on reconstruction of electron micrographs it was proposed that a midget bipolar/midget ganglion cell pathway carries the blue-OFF signal (Klug, K. *et al.*, 2003). Receptive fields of blue-OFF cells are however larger than PC cells in the marmoset LGN, which makes this possibility less likely (Szmajda, B. A. *et al.*, 2007). Also, an immunocytochemical stain for off midget bipolar cells could found no S-cone contacts (Lee, S. C. *et al.*, 2005).

Physiologically, blue-OFF cells have type 2 (coextensive) receptive fields and a temporal response extending to 20–30 Hz (Yeh, T. *et al.*, 1995). Again it is likely that a central low-pass filter attenuates the frequency response.

A large bistratified cell also carries a blue-ON signal (Dacey, D. M. and Packer, O. S., 2003). This is a rare cell type and has not been extensively described. There are no indications from *in vivo* measurements of a dual blue-ON population, but it could be that these cells are very rarely encountered. S-cone inhibitory input is also present to the melanopsin containing ganglion cell (Dacey, D. M. *et al.*, 2005) but its contribution to color perception seems likely to be minimal.

1.21.6 Conclusions

Blue-ON cells correspond to the small bistratified ganglion cell type, but there are other ganglion cells with S-cone input which are likely to contribute to the blue–yellow channel of perception of color. This

is an evolutionary ancient system. Although to a first approximation cell responses can be described as a difference signal between S- and M,L-cone inputs, some features of this pathway are still poorly understood, in particular its characteristics during chromatic adaptation.

Glossary

autocorrelogram Plot of the spatial position of all cells of a given type within the field relative to every other cell of the same type.

coverage factor The product of dendritic field area and cell density for a given cell type

cross-correlogram Plot of the spatial position of all cells of one type within the field relative to every other cell of a second type.

Delaunay segment Distance between any two cells that share a Voronoi border; the Delaunay triangulation of a population of cells is comprised of all such Delaunay segments between cells.

density recovery profile The spatial density of cells in the autocorrelogram as a function of distance from the origin.

effective radius The radius of the exclusion zone defined by the density recovery profile.

exclusion zone The region surrounding a cell where the probability of encountering a like-type cell is lower than the mean density for that cell-type.

packing factor Scale-independent measure describing the extent to which a mosaic of cells varies between a random distribution of points and a hexagonal lattice.

packing intensity The extent to which a population of cells covers the retinal surface by nonoverlapping fields with a size equal to the exclusion zone.

regularity index Scale-independent measure describing the variance within a population of nearest neighbor distances or other tessellation-based attributes (e.g., Voronoi domain area).

Voronoi domain Territory associated to a cell that is closer to that cell than to any other homotypic cell in the field.

1.22.1 Introduction

The visual field is sampled by a sheet of nerve cells composed of multiple types, each contributing uniquely to the postreceptoral processing of the visual signal. Each of these cell types is distributed across the retinal surface as a patterned array, extending dendrites that sample from the layer of afferent innervation within a plexiform layer. The morphological configuration of those dendrites and the extent to which they overlap one another are unique for each cell type, being associated with the functional contribution carried out by each population at every location across the retina. The present chapter will consider the extent to which such patterning and dendritic overlap are regulated in order to ensure a uniform coverage of the retinal surface.

1.22.2 Retinal Mosaics

1.22.2.1 Global Variations in the Distribution of Retinal Nerve Cell Types

The densities of different types of retinal neurons vary across the retinal surface in a manner that is both species- as well as cell-type specific. For example, ganglion and cone photoreceptor cell density in the primate retina both show a steep decline outside the perifoveal region, whereas dopaminergic and cholinergic amacrine cell density decline far less conspicuously as a function of eccentricity (Mariani, A. P. *et al.*, 1984; Perry, V. H. *et al.*, 1984; Curcio, C, A. *et al.*, 1990; Dacey, D. M., 1990; Rodieck, R. W. and Marshak, D. W., 1992). Figure 1 shows comparable results from the cat retina, in which the cell density profile as a function of eccentricity from the area centralis is unique for each cell type (Steinberg, R. H. *et al.*, 1973; Wässle, H. *et al.*, 1978; Hughes, A., 1981; Vaney, D. I. *et al.*, 1989). Other species, for example the rabbit, exhibit a visual streak rather than a single central area associated with the direction of gaze, in which cell densities are maximal along a horizontal strip of retina, falling off at different rates as a function of eccentricity for the different cell classes (Masland, R. H. *et al.*, 1984; Brecha, N. C. *et al.*, 1984; Massey, S. C. *et al.*, 1991; Mills, S. L. and Massey, S. C., 1991, 1994; Vaney, D. I. *et al.*, 1991; Young, H. M. and Vaney, D. I., 1991). Still other species like the mouse exhibit relatively minor changes in cell density across the retinal surface for most cell types (Jeon, C-J. *et al.*, 1998).

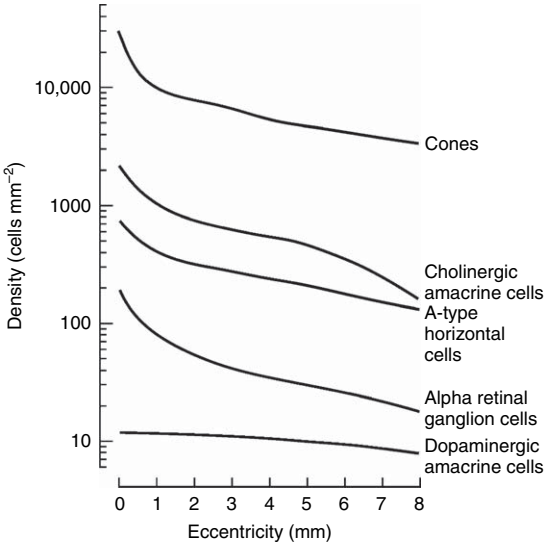

Figure 1 The density of different retinal cell types decreases as a function of increasing eccentricity in the cat's retina, but the rate of decline as a function of eccentricity is unique for each type of cell. Cones show the steepest decline outside the area centralis, while dopaminergic amacrine cell density shows relatively minor variation across the retina. Adapted from Vaney, D. I. 1985 The morphology and topographic distribution of AII amacrine cells in the cat retina. Proc. R. Soc. Lond. B. 224, 475–488, with permission from The Royal Society, London.

1.22.2.2 Local Patterning in the Distribution of Retinal Nerve Cell Types
